Several interesting cases stand out. Chief among others was my own case. During the winter of 1908 while suffering from an attack of influenza, I was called out to a confinement in the bush. Owing to the roughness of the roads, driving was only possible for eight miles; riding had to be resorted to for the other three in a driving, sleety rain. On returning home I was thoroughly chilled, and though I took several whiskies and toasted myself before a log fire, I could not get warm. At two o'clock in the morning I had a rigor which lasted more or less for several hours; this was accompanied by sharp stabbing pains in the left side; my temperature ran up to 105° F. The respirations were 40, and the pulse was 120. The bottles containing the drugs were brought to me, and I made the mixture up for myself, taking a dose every hour for six doses, then every two hours for another six doses. By six o'clock in the evening the temperature was down to 102.4° F.; the respirations were 32, and the pulse was a little over 100. The pain in the side had been mitigated greatly after the application of a kaolin cataplasm. The nearest doctor was unable to put in his appearance till nine o'clock that evening. By that time I was fairly comfortable and was sweating quietly about the head and neck. The next day my temperature was down to 101° F. There was a profuse rusty sputum and the pain in the side was almost gone. My respirations continued about 30 for the remainder of the week, but my temperature fell to normal by lysis on the fourth day and, though somewhat irregular, between that and 99, it never rose again.

A series of nine cases was attended while acting as locum tenens in a country district of Tasmania. These patients were all widely separated by divergent routes and it was impossible to see more than half of them each day. The nursing in most of them was of the crudest, generally devolving upon the wife or mother of the patient, but notwithstanding the difficulties and the want of proper attention, all came through their illnesses successfully.

A very striking cure was recently seen in a case of pneumonia supervening upon fulminating appendicitis. The operation was performed by Dr. George Horne, and the next morning a severe type of pneumonia had developed. Phosphorus was immediately exhibited following the method usually adopted, that is, small doses repeated hourly for six doses, then every two hours for another six doses, then every three hours till such time as the patient is well enough to discontinue. Within twenty-four hours the boy was out of danger from the pneumonia. Notwithstanding the fact that the wound, which was well drained, broke down and fecal discharge was profuse for several days, the boy returned to his home perfectly well three weeks from the day he entered the hospital.

The usual prescription for pneumonia in all its branches is as follows:

B. Tincture phosphori (1:1000) .......................... 3ss; J.
Liquoris ammonii acetatis ................................ 3;
Spiritus aethers nitrosi .................................. 3ss;
Aquaeq. s. ad ............................................. 3vi;

M. et Sig.: Dessertspoonful hourly for six doses. At alternate hours for six doses; then every three hours till crisis.

While this prescription is the standby, strychnine injections and spirits are administered when necessary, and kaolin cataplasms, or poultices are applied locally as the case may demand. During convalescence, particularly after bronchopneumonia, the prescription as given for tuberculosis is often administered with the object of fortifying the patient against any after weakness.

ACUTE AND CHRONIC BRONCHITIS.

The invaluable aid that phosphorus has been both in tuberculosis and pneumonia suggested, quite early, its tentative administration in all cases of bronchitis, acute and chronic, it being added as an ingredient to bronchitic mixtures. In the acute stage it soon brings about a breaking down of the hard useless cough, and as a rule within twenty-four hours the cough becomes soft and the sputum profuse, while the second stage is considerably shortened and patients are well long before they would be if under ordinary treatment. In chronic bronchitis the attack is rapidly relieved and patients who have been more or less subject to this ailment soon attain a state of partial or actual freedom.
from the disease. It seems to act in a direct manner on the lung itself, because these cases, which have been troublesome and stubborn in their reaction to ordinary treatment, show a marked improvement in a very short time.

SUMMARY.

Phosphorus has been successfully administered in all classes of cases of lung disease during the past eleven years, and though, in the majority of the cases it has been used in combination with other drugs, occasionally necessity compelled the use of it alone, and it is obvious that the success which has attended all cases in which it has been used has been largely, if not altogether, due to its presence in the mixture.

What the precise action of phosphorus is it is impossible to state, but in view of the foregoing it would be interesting to have a physiological research made into its action on healthy and diseased lung tissue. One is convinced, however, that while it has a direct action upon the lung tissue—which perhaps accounts for its rapid effects in acute bronchitis and pneumonia—there is also a probability that the tendency toward tuberculosis is generally, particularly so in the wasting diseases. The patients not only improve as regards the lung but their whole bodily condition shows renewed vigor and capability of standing against the onslaughts of their disease. This suggests the possibility that the tendency toward tuberculosis is brought about by a great lack of phosphorus in the nervous and other tissues of the patients. Whatever or however its action, its results as shown in this paper have been of a very beneficial character and, it is hoped that in thus giving these experiences of some of my fellow practitioners will be induced to give this drug a thorough trial in all cases of lung disease, particularly so in tuberculous disease of the lungs.

90 Collins Street.

NOTES ON THE RESPONSE OF VEINS TO EPINEPHRIN.

By Albert C. Crawford, M. D.,
And Margaret M. Twombly,
Stanford University, California.

From the Laboratory of Pharmacology, Leland Stanford Junior University.

We have been interested in the study of the physiological explanation of the bluing of the cock's comb by ergot. At first we believed it was due to an active venous dilatation, but as yet have not been able to prove this by oncometric measurement; hence, we decided to see if active venous dilatation could be induced by the action of certain drugs on the isolated veins.

Vasomotor nerves have not been positively proved to be present in veins, but we argued that they were pre-existent, and that the vasodilator fibres probably predominated. It has been shown that epinephrin will act on the extreme terminals of vasomotor nerves, and, if these are inhibitory in character, will relax the vessels, while if they are of constrictor quality it will constrict the vessels. Hence, a response to epinephrin would indicate the presence of vasomotor nerves.

This action can be proved by using strips of bloodvessels by Meyer's method. Rings were taken from the jugular vein of white Leghorn roosters. Contrary to our expectations, the rings taken at about the middle of the neck contracted slowly, but markedly, in an oxygenated Ringer's solution. The taken near the head gave no response, and a similar negative result was obtained with rings taken from the large veins of the wattle. Therefore, we would argue the absence of a vasomotor supply to the veins of the wattle and cephalic end of the jugular vein and, perhaps this absence of vasconstrictor fibres in the wattle may be one of the reasons why they blue easily.

At the time this work was begun there was only one report as to the action of epinephrin on mammalian veins, that of Meyer (1). He reported that strips taken from the jugular vein of oxen contracted to some extent.

We found that isolated rings of the femoral, iliac and saphenous veins of dogs also contracted. Recently we have noted that Gunn and Chavasse (2) have been carrying on experiments with the veins of mammals, and have obtained similar results, so that this portion of our report must be considered merely as corroborative of their work.

SO CALLED LATENT SYPHILITICS, OR PARETICS AND TABETICS: A WATER SUGGESTION.

By J. C. Minor, M. D.,
Hot Springs, Ark.

President of the Board of Health; Surgeon General, Arkansas National Guard.

A dirty sponge when soaked well with water can be cleaned. Without the soaking there will and must remain in the interstices of the fabric whatever waste and foreign matter may have been introduced. Fill the sponge with water and squeeze it; out comes the foreign matter. Continue this process, and after a time the sponge is clean. The human body is a sponge with millions of interstices that may become receptacles for foreign matter. Some of the tissues of the human body are dense—the brain, for instance, and the nerve structures generally, as well as the joints and tendinous and ligamentous structures. From this class of dense tissues lodgments of foreign matter will be liberated and eliminated with more difficulty than from looser tissues, such as the muscular tissue, from which these lodgments may be delivered to the emunctory system by ordinary massage.

I am led to express this idea after reading the editorial in the Interstate Medical Journal of May 1913.
13, 1913, in which comment is made on Dr. William W. Graves's paper read before the St. Louis Medical Society, on April 19, 1913. My remarks are in no way to be construed, I would have it understood, as criticising Doctor Graves's splendid report of his investigations, but rather to suggest a practical view, in addition to the scientific view taken by the profession.

"Latent or dormant syphilis of the cord" simply means, it seems to me, that the spirochetes of long years ago have been harbored in the dense tissues and have not been dislodged by the free emunition to be brought about by a systematic inhibition of water to flush effectively the four emunitions—skin, kidneys, bowels, and lungs—while the necessary medication was being used. We cannot flush sewers without water. It makes little difference whether the toxemia be posttyphoid, postsyphilitic, postdiphtheritic, or a toxemia from absorption of toxins from the small or large intestine or from other sources. There are but four channels of emunition, and we cannot get free emunition without water (approximately seventy-five per cent. of the normal weight of the body) in the system.

Many of our patients are below the normal weight. We must remember that food gives weight to the body only when transported to its destination by the requisite amount of water to keep up the body weight. Low weight, then, means an insufficient amount of water in the body. Lack of resistance to disease means that the food taken has not been delivered to its destination with the proper amount of water. Unless there is an adequate circulating medium (the proximate principle, water), it will be difficult to furnish the body with nutrition and much more difficult to rid the same body of a toxemia or the medication used in combating it.

Many of us observe unfavorable and often disastrous sequelae from the use of the formula familiar to us as "666," or of mercury or of quinine, and many other potent remedies, but these valuable remedies with their havok in the system, their unknown destruction and known destructive efforts, must be eliminated with the good work they have wrought, or else we have, or may have, deposits of their detritus pent up in the remote and dense structures of important organs of the body. The patient may be burdened with more waste and more dangerous waste than the toxemia itself might have caused.

The gist of this article is to ask for good elimination pari passu with the administration of drugs of so potent a character as salvarsan, mercury, serums, etc. Many cases of latent specific neuroses may be thus avoided.

## PRIZE QUESTION CXXXV.

**THE TREATMENT OF BURNS.**

(Continued from page 283.)

Dr. C. E. Montgomery, of Walla Walla, Wash., considers that:

The treatment of this deplorable condition is naturally divided into four stages as follows: 1. Treatment of the shock and pain. 2. Treatment of the wound. 3. Treatment of the toxemia from absorption and lack of elimination. 4. Prevention of deformity by excisitral contractions.

When a physician is called to see a burned patient he is first confronted with a condition of shock proportionate to the severity and location of the burn. This condition first comes about largely as a result of fright, and then the continued irritation from the pain impulses reaches the brain and overpowers the vasomotor equilibrium. In children this is especially true. The first indication is, of course, to cut off the volley of pain impulses, and the best drug for this is undoubtedly morphine given hypodermically in the appropriate dose, instead of...
strychnine, as is so often given for the circulatory disturbance of the shock. If the blood pressure remains low or unevenly distributed after the morphia has been administered, a normal saline injection per rectum, or otherwise, will reestablish it, if at all possible.

Coincident with the alleviation of the pain by the opiate, is its relief by a dressing, which should be soothing, feebly antiseptic, and nontoxic.

If the burn covers a considerable surface it is not wise to spend unnecessary time in attempting to thoroughly cleanse the burned area before adding the first soothing dressing, for by so doing the shock is greatly increased and the infection is not imperceptibly lessened. It is well to irrigate the surface rapidly with a feeibly alkaline solution such as sodium bicarbonate (one drachm to the pint), or to irrigate with a mild soap solution, which will cleanse and is nontoxic.

For a first dressing, I prefer a bland ointment base, to which may be added such ingredients as the particular burn requires. There is nothing more soothing or grateful to a burn than an antiseptic ointment; the ointment should be heated and rolled bandages placed in the liquid ointment until they are saturated. Then the wound should be rapidly bandaged, and over the ointment bandage a layer of cotton lint or a plain bandage may be applied. A dressing of this kind is easily removed, provided a sufficient amount of ointment has been used. Any good ointment base with picric acid, ichthyol, or even cocaine or extract of opium may be used and the strength regulated according to the amount used and the surface covered.

The next thing that appeals to the physician after the shock is relieved and the wound dressed is to aid elimination by making use of the reciprocating organs. Toxicity must be reduced as far as possible by cleansing the bowel thoroughly, and by stimulating the liver and kidneys as well as the uninjured skin. A brisk saline purge relieves the bowel quickly and also has a nonirritating stimulating effect upon both the liver and kidneys. As soon as the bowels are relieved, normal saline should be repeatedly given per rectum, for it dilutes the toxic substances within the blood and saves the kidneys from its irritant effect. The skin is also stimulated to elimination by a hot saline solution.

The wound must be redresed and cleansed to remove the toxic surface so far as possible. Irrigations with a very dilute picric acid solution are useful for this, after which the dead skin and flesh should be trimmed away and the dressing reapplied, or if the integument is so largely destroyed as to necessitate skin grafting the area is cleansed and the skin grafts applied. Grafting is always advisable provided a granulating surface or one supplied with blood can be had, but it is useless to place skin grafts upon a surface with a layer of burned or devitalized tissue between the graft and the blood supply, for grafts so placed soon decompose and add to the toxicity of the wound.

If granulations become exuberant, slightly astringent irrigations such as a solution of aluminum acetate gives good results, and if there is a tendency to overgranulation a dusting powder of zinc stearate with boric acid, acetanilide, or arsaniol will cause the overgrowth to stop and a scab to form. After the scar tissue forms it has a tendency to contract and produce great disfiguration. This can be overcome to some extent by limiting the size of the scar by using all means to promote rapid healing, by skin grafting; and by drawing the unburned edges of the wound as near together as possible, even if small slits have to be made in the skin to allow it to be brought further over the denuded area. The skin can be drawn and held over the surface by adhesive plaster strips properly applied.

Aside from the cicatrix on the skin, there is apt to be deformity of the joints by ankylosis, and this should be prevented by placing the leg or arm in the most desirable position should ankylosis occur, and then prevent the ankylosis if possible by passive motion of the joint at frequent intervals. If the knee is burned the leg is usually flexed, and should firm ankylosis occur the member is of little use to the individual; by forethought on the part of the physician the limb can be kept in an extended position, so it is useful even if ankylosed. This position should be maintained by a Buck's extension instead of by casts or splints, for this will serve the double purpose, pulling the injured joint surfaces apart, and thereby make it more difficult for firm ankylosis to occur.

Dr. Meyer A. Rabinowitz, of Brooklyn, observes that:

The treatment is both constitutional and local. Constitutional treatment is of prime importance in order to combat pain and shock. A hypodermic injection of 3/4 grain of morphia and 1/100 grain of atropine—adult dose—should be given in all severe cases, and repeated if necessary. The patient should be gently transported to his bed, and the clothing then removed—best by cutting away his clothes where too much handling is otherwise needed. The following stimulants will be found of decided value especially for hypodermic use: Caffeine; sodium salicylate, five grains; strychnine sulphate, grain, 1/30; saturated solution of camphor in sweet almond oil; epinephrin solution (one to 1,000), fifteen to twenty minims, intravenously. If patient can swallow give plenty of fluids by mouth; otherwise give an intravenous injection of saline or administer saline per rectum by Murphy drip method.

Local treatment of the burn is in order when pain and shock have been overcome. If the lesion is at all extensive in size or degree of severity, or in an uncleanly condition, the preliminary cleansing must be done under an anesthetic to be at all thorough or permit of antisepsis. Cleanse the area thoroughly with soap and water, then with gasoline or benzine; then sponge off with sterile cotton pledges medicated with one to 2,000 bichloride of mercury solution, or one half per cent. compound solution of creosol. Remove all debris and trim off all dead skin, leaving all blisters intact. Then mop surface dry with sterile gauze. In the preliminary cleansing do not render the surface antiseptic with tincture of iodine, as it may cause severe blistering of the skin, and don't puncture the blisters.

The preliminary dressing should consist of sterile gauze soaked in an antiseptic solution kept in place.
by a gauze bandage, and the dressing should be moistened without removal from time to time, except in the case of picric acid solutions. The following solutions meet all indications: Normal saline; sodium bicarbonate, one tablespoon to the quart of sterile water; (picric acid, six parts; alcohol, sixty parts; sterile water, up to 1,000 parts). The last solution should not be used in lesions of great extent or depth for fear of toxic results from absorption. With these limitations it is beyond doubt the best available solution in burns. Do not use Carron oil because it is septic, or phenol solution because of its marked toxicity and renal irritation, or Burrow’s solution, because of the danger of lead poisoning, or ointments except where the skin is intact. The preliminary dressing should not be removed before the third or fourth day without special indication.

Subsequent dressings should be as follows: Remove the preceding dressing; mop surface free of discharge with cotton sponges soaked in a one to two thousand bichloride solution; open blisters aseptically and evacuate the serum, but leave skin forming the blister; trim off dead pieces of skin; then cover the entire denuded area of skin with narrow strips of rubber tissue, previously soaked for a day in a one to one thousand bichloride solution, with edges overlapping; this in turn covered with dry sterile gauze and bandage. This dressing should be changed as often as is necessary to keep the surface clear of pus, removing the cotton gauze and pieces of rubber tissue that do not adhere to the skin, and irrigating the surface with saline or boric acid solution. Do not use strong antiseptics or dry bandage next to granulating surface or prevent healthy granulations rapidly forming new skin. Where the granulations are sluggish and epidermization is slow, the use of scarlet R in four per cent, ointment form to the edges of the patch will work wonders. Only if separation cannot occur in denuded areas should Thiersch grafts be used, and the covered over area of grafts is kept free of bandage and exposed to the atmosphere to get the quickest and best results.

Where the entire area of the burn, either at the very beginning or the very end, consists only of an erythematous area, then only are ointments or powders useful: Boric ointment, bismuth subgallate, or thymol iodide. Should the burn become infected use locally a five per cent. solution of boric acid and measures to combat sepsis. Toxemia due to the burn, nephritis, and Curling’s ulcer of the duodenum are to be treated according to indications.

Dr. Frank Levison, of Portsmouth, Va., says that:

In the treatment we must consider the local condition, the constitutional symptoms, and the sequel.

In first degree burns there is apparently very little destruction of tissue; the chief indication of treatment is the relief of pain. The use of any non-irritating ointment, as boric acid (one drachm to one ounce of petrolatum), or mentholated petrolatum is followed by prompt recovery.

In second degree burns the relief of pain and prevention of shock are the chief indications. Morphine, grain ½; strychnine, grain 1/30; should be given by hypodermic. The use of atropine will check the secretion, which is a contraindication in burns, as we want to keep all channels of elimination wide open.

There are various methods of treating the local condition: The application of ointments or dressings, soaked with oily substances, of which Carron oil is the most frequently used, which protect the burned surface from exposure to the air and from change in temperature; the application of mild antiseptic solutions on gauze, which must be kept constantly wet, or may be allowed to dry, as aluminum acetate solutions and picric acid solution; the application of various dusting powders, leaving the burned part exposed to air in order to become dry and favor crust formation.

In second degree burns the application of dressings of sodium bicarbonate in saturated solution, or in a weak solution (five grains to the ounce of water) is useful. Aluminum acetate solution (twenty grains to the ounce of water) poured on gauze and placed on the wound and kept constantly wet with normal salt solution, is frequently used.

Picric acid, one per cent. aqueous solution, I have found to give me best service. This application (picric acid, fifteen grains; alcohol, two drachms; water, six ounces), on gauze, to the wound, should not be touched for three to four days. After this a second application of the same solution should be left on the part for a week or ten days. This dressing makes the patient feel very comfortable and lessens the pain, although at times it may increase the pain. A one per cent. solution of picric acid is safe in first and second degree burns. The chief dangers are in children, and the application of the solution to large surfaces; absorption of picric acid may take place. If absorption and poisoning is taking place the urine is dark and cloudy; albuminuria, pigmented and yellow skin, some diarrhea, and some elevation of temperature, are present.

The application of Carron oil has the great disadvantage of not being aseptic, and besides being a filthy dressing, pus formation frequently occurs.

These disadvantages to a great extent can be eliminated by using a modified Carron oil, consisting of:

B. Olei eucalypthi, 3 ss; Olei olivae, 3 xv; Liquor calcis, q. s. ad... Oil.

M. Phenol, from one half to one quarter grain, may be added to each ounce of this prescription, if the burn is very painful.

Of the ointments ichthyol, fifty per cent., is one of the best. I usually use the following with good results:

B. Ichthyolis, 3; Thymolis iodidi, gr. xx; Aepis lanii, 1 ad q. s. ad... Oil.

M. Petrolatii, 44.

In third degree burns the treatment is practically the same as in those of the second degree. The use of picric acid solutions is very good, but requires watching of the patient for the development of poisoning.

If the area is very large apply a warm saturated solution of sodium bicarbonate or aluminum acetate solution, kept constantly moist. If the dressing
becomes saturated with pus and serum, it should be changed. Sloughing tissues should be cut away when they become loose.

If the burnt area is very painful, I usually irrigate the wound as thoroughly as possible with normal salt solution or a saturated boric acid solution, and then, when dried, apply a dusting powder. After the acute inflammation has subsided, and the wound is clean, if it heals very slowly a dilute solution of silver nitrate is good to stimulate the granulating surface.

I have found scarlet red ointment, used cautiously, of particular value. Balsam of Peru, one drachm to one ounce of scarlet red (five to ten per cent.) ointment has given me good results in slowly granulating ulcerations. The ointment is applied very thinly at the margins of the granulating walls. The surrounding healthy skin should be protected by the application of some bland ointment, such as boric acid or zinc oxide. This dressing should be left on the surface for twenty-four to thirty-six hours only, and then the whole surface should have an application of some bland ointment for two days. The scarlet red should then be reapplied, as stated above. This ointment frequently causes a dermatitis, and therefore should be used with care on the tissues which are already damaged. Where the destruction of tissue is great, early skin grafting by Thiersch’s method should be resorted to, as this will lessen the deformity to a great extent, and the surfaces will heal in a shorter time.

Fourth Degree Burns—When great charring is present amputation of the part is required.

General Management—In second and third degree burns the great pain and shock requires first attention. If large surfaces are burned remove the clothing with care, cutting it away if necessary, give morphine hypodermically, and also stimulate the patient. Opium or morphine should be given at bedtime, otherwise the patient will not sleep on account of pain. Place the patient in a warm bath, particularly if chill is present. To the water some sodium bicarbonate may be added; apply hot water bottles to the extremities and keep the patient warm with light blankets, to prevent the loss of heat.

The diet should consist of easily digestible and concentrated foods. Milk should be given in large quantities. It is of great importance to keep the skin clean, so that it will be able to eliminate freely and not throw the bulk of the work on the kidneys. Water should be taken in very large quantities, so that the toxines will be eliminated more freely, and more diluted, and will not be so destructive to the kidney structure. The bowels should be kept open, two or three watery stools a day; this will also cause increased elimination of toxines. Magnesium sulphate is very good for this purpose. Large doses of potassium citrate, or citric acid, should be given; a solution of thirty to forty grains of citrate to two drachms of ammonium acetate every three to four hours, not only causes a lowering of temperature in the reactionary fever, but will cause increased action of the skin and of the kidneys, and therefore an increased elimination of the toxines. As there is a great tendency toward the clotting of the blood, and

of damage to various structures and organs, due to the clots, citric acid and the citrates are given to lessen the coagulability of blood and to prevent this threatened damage to the organic structures. The brain congestion which frequently follows burns should be treated by rest and quiet in bed, with head and shoulders elevated, hot foot baths, a sinapism to the chest and the calves, and free purgation. The application of cold to the head and a hot water bottle to the feet is often beneficial. The diet should be liquid and no alcohol should be given.

Ulcration of the intestines near the papilla of Vater (Curling’s ulcer of the duodenum) occurs in large surface burns, and should be treated as any other ulcer in that region.

Deformity—In cases where two contiguous surfaces are burned they should be separated with gauze, as in cases of burns of fingers, etc., to prevent the webbing together of the two surfaces. Deformity is prevented to a great extent by the early use of skin grafting and the early application of splints—not when the contraction and deformity have already occurred.

Therapeutical Notes.

Treatment of Pulmonary Embolism.—Oppenheim, in Progrès médical for February 15, 1913, after referring to the importance of prophylaxis with regard to lung embolism, states that where embolism has actually taken place the following symptomatic measures will alone prove of value:

To overcome dyspnea, and the tendency to syncope injections of camphor and ether should be given every hour:

R Camphora. ............... 3v (20 grammes)
Aethers, ............... 3viss (25 grammes)
Olei olive sterilisati, q. s. ad. .......... 3viss (100 c. c.)
M. Sig.: Give hourly injections of 30 minims (2 c. c.).

One or two litres of oxygen should simultaneously be injected under the skin, and their effect kept up with repeated oxygen inhalations.

Next, dry cups should be applied to the chest, and if hemoptysis is not marked, from four to six of the areas may be scarified on the side that is subjectively painful. Venesection is indicated only where there are evidences of pulmonary edema. Where pain is not relieved by the cupping an injection of morphine should be given, to be immediately followed by one of ether or sparteine.

Cough, which is generally marked, should be assiduously combated, as it increases dyspnea and favors hemoptysis:

R. Extracti opii .................. gr. 1/2 (0.01 gramme)
Extracti hysocyami, .................. 1/4 gr. 1/12 (0.005 gramme)
R. Fiat pilula No. i.
M. Sig.: One pill every two or three hours.

To prevent, in so far as is possible, suppuration or gangrenous degeneration of the infarct, a tablespoonful of the following mixture may be placed in a vessel containing water that is kept boiling:

R. Olei thymi, .......... 3iiss (30 grammes)
Olei eucalypti, .......... 3iiss (30 grammes)
Olei terebinthini, .......... 3iiss (30 grammes)
Tinct. benzoini. .......... 3iiss (30 grammes)
Alcoholis, q. s. ad. .......... 6vii (250 grammes).
Misc.
Another available procedure is to pass the oxygen that is being inhaled by the patient through the following combination, contained in a flask:

Répéthyroid, Eucalyptol, Phenol, Alcohol eau solut., Acqua, q. s. ad. 0.25 (1000 grammes).

Misc.

In exceptional cases surgical intervention—Trendelenburg's operation—can be undertaken.

Uses of Ovarian Extract.—S. Wyllis Bandler, in the Archives of Diagnosis for January, 1913, states that in certain forms of dysmenorrhea, which he ascribes to a mild degree of hyperthyroidism, ovarian extract is of great value. He has also found it useful in lactation, atrophy of the uterus, and in the flashes of the climacteric period, natural or artificial, especially if administration is begun early. In anemias, including genuine chlorosis, it also served well. Combinations of iron, arsenic, and ovarian extract are particularly useful in such cases; wherever iron is indicated the author gives ovarian extract with it. In amennorrea, relative or absolute, he has found the ovarian preparations the best remedy. They produce no untoward results and the main contraindication consists of profuse bleeding. Bender often combines ovarian extract with thyroid, especially to promote metabolism and encourage oxidation. The annoying symptoms sometimes produced by thyroid are often greatly diminished by the addition of the ovarian extract.

Treatment of Vernal Conjunctivitis.—Aaron Brav, in the Therapeutic Gazette, April, 1913, states that the treatment of this affection is essentially palliative. At the first visit he prescribes a mild astringent:

Ré Bézoar, Zinci sulph., Acidi borici, Aqve destillate, q. s. ad. 0.25 (100 grammes).

M. Sig.: Bathe the eyes thrice daily.

In the intervals the eyes should be bathed with ice cold water, to relieve the burning and itching. One drop of a dilute solution of an organic silver preparation may in addition be instilled three times daily.

The best office application is a twenty-five per cent. solution of boroglyceride. This is used every other day at first, and the interval then increased as the patient improves.

After a week or two of this treatment, the following lotion is employed:

Ré Acidi borici, Epinephrin (1:1000 solution), Holocaine, Acqua camphora, Aqve destillate, q. s. ad. 0.25 (100 grammes).

Fiat solutio. Filtra.

The author also prescribes:

Ré Glyceryt glycoroglycerini, 0.25 (15 grammes).

M. Sig.: One drop in each eye three times a day.

This preparation causes burning, but a soothing effect follows, and itching is entirely relieved.

To prevent adhesion of the lids, some hydrated wool fat or petrolatum, simple or medicated, should be applied at night time. For photophobia smoked glasses should be advised.

Surgical interference is probably only warranted where there are present large papules with a pedicle; these had best be removed with curved scissors.

To prevent recurrences it is best to continue treatment during the winter season. The patient's general condition must be looked after, as some constitutional dyscrasia is an important predisposing factor. For children the following tonic is useful:

Ré Syrpi ferri iodidi, Liquoris potassi arsenici, Syrupi hypophosphitum composition, 0.25 (4-8 grammes).

Essentie pepsi (N. F.), q. s. ad. 0.25 (100 grammes).

M. Sig.: One teaspoonful three times daily.

Treatment of Gonococcal Urethritis.—S. H. Likes and H. Schoenrich, in the Urological and Cutaneous Review for February, 1913, refer to the fact that while anterior gonorrhoea may at times run an obsteinate course, it is by no means as troublesome as the complications likely to occur when the posterior urethra has become involved. In anterior cases it should be the aim to avoid the spread of the infection to the posterior urethra.

To this end the authors have devised a simple apparatus, consisting of a moveable upright rod or prop and a platform with an horizontal extension provided with notches, the latter regulating the height of the prop to suit patients of different stature. The patient stands on the platform, with his back turned to the prop and notched extension, and places the prop, which is provided with a V shaped padded crotch above, in such a position that upward pressure is made upon the perineum just anterior to the anus, thus occluding the membranous portion of the urethra and shutting off communication with the posterior canal. With the fingers closing the meatus, any injection fluid introduced is thus in a closed tube and can easily be retained for an indefinite period. The anterior urethra will be distended and penetration of the fluid into the follicles and glands favored, thus affording it a real opportunity to destroy the deep lying gonococi. The authors believe after many years' experience with this device, that it hastens the cure of anterior urethritis and thus in many cases prevents extension of the process to the posterior urethra.

Relief of Pain in Tuberculous Laryngitis.—Boulié, in Journal de médecine de Paris, April 19, 1913, is credited with the following formula for sprays to be used in relieving dysphagia in laryngeal tuberculosis:

I.

Ré Phenolis, Cocaine hydrochloridi, Glycerini, Aqve destillate, 0.25 (225 grammes).

M. ft. solutio. Solutions.

II.

Ré Morphine hydrochloridi, Antipyrina, Acasa lactis, 0.1 (2 grammes).

M. ft. solutio. As an instillation, the following may be used:

Ré Morphine hydrochloridi, 0.2 (1 grammes).

M. ft. pulvis.
DO THE KIDNEYS PRODUCE AN INTERNAL SECRETION?

Gradually, as precise methods of investigation are contributing reliable data, the many internal secretions which were formerly thought to exist as separate entities are now being reduced in number. Indeed, if the glands known positively to produce such a secretion were enumerated, the list would be surprisingly small. Among those organs which are steadily losing ground in this connection are the kidneys.

The belief that the kidneys are the source of an internal secretion dates back to 1869, when Brown-Séquard showed that injections of renal extract postponed the development of uremia in nephrectomized animals and prolonged life. Lépine found in addition that a filtrate of a watery extract of kidney caused a rise of temperature and dyspnea. Moreover, Oliver and Schäfer ascertained that a cold water extract of fresh kidney, when injected intravenously in rabbits, soon produced a more or less marked rise of the blood pressure. These various observations have been amply confirmed.

In the light of recent data, however, all these phenomena can as readily be attributed to physiological substances which normally form part of the renal tissues and fluids as to any supposititious internal secretion. As is well known, hypernephroma of the kidney are developed from adrenal rests in the renal substance, while the adrenal active principle is now known to be found in the blood throughout the entire organism, including, therefore, that of the kidneys. That an extract of the latter should contain the adrenal principle is, therefore, self-evident. This fact being borne in mind, all the phenomena attributed to the so called renal internal secretion are found to coincide precisely with those awakened by the adrenal product. The elevated blood pressure witnessed is a familiar effect of the latter; the rise of temperature was not only noted as a concomitant effect by Reichert, Lépine, and Morel, but Fuchs and Roth found recently that adrenalin increased markedly the intake of oxygen and the output of carbon dioxide. As to the dyspnea and the ensuing arrest of respiration, obviously due to toxic spasm of the respiratory muscles, it has also been found to be a characteristic effect of adrenal extracts by Oliver and Schäfer, and more recently by Langlois and Garrelon. Even Brown-Séquard’s observation that renal extracts postponed the development of uremia in nephrectomized animals and prolonged life falls in presence of the fact, shown long ago by Langlois and developed by others since, that adrenal extracts are endowed with antitoxic activity—an essential feature in combating uremia, itself due to retained poisons. Finally, Lewandowsky has shown that the effects ascribed to a supposed renal secretion could be obtained with venous blood derived from any other structure of the body.

On the whole, the evidence is decidedly against the existence of a renal internal secretion, and it is hoped that the true status of other organs credited with such will soon be established. Then will it be possible to realize how truly important to the organism at large are the bona fide internal secretions.

THE PROLONGATION OF LIFE.

Up to within recent times the search for the longer life has been merely a groping in the dark, and following no definite course. It was largely a search by individuals from most selfish motives and without even an attempt at concert, and it remained for the science of the advanced modern type to place this quest in the category of the material, to be sure, but of value to the community at large as well as to the individual. Civilization has for its greatest achievement, and almost entirely through the medical sciences, the conservation and the prolongation of life. The goal is to breed a race of longest life, of most efficiency, and with the least
possible waste. During the ages when constant warfare and its mate, the ever present epidemic, wiped out whole peoples, life had no value other than as a subject for destruction. Then the average span of life was about twelve years. But with the dawn of enlightenment, promiscuous warfare is gradually ceasing, and the advances in the science of life have progressed so rapidly that we have been able to reach the present high average length of life.

And now, even after these adverse conditions have been overcome, the death rate is yet too high. A high infant mortality still confronts us, though even here there is a large improvement upon previous conditions. Typhoid fever, cancer, and the degenerative diseases form a very large proportion of the death rate. In recent years, however, typhoid fever has been reduced about forty per cent. On the other hand, cancer has risen over 100 per cent., and the public and the profession are now fairly alive to the danger, and are enthusiastically taking up the campaign of education along the lines of prevention.

Industrial diseases form a very large drain on life. In recent years the growth of the industries has been so rapid that the development of safety provisions is unable to keep pace with them. As fast as possible, however, remedial measures are shaping themselves and results are already manifesting themselves in the remarkable decrease in the death and disease incidence in these industries. The health authorities have taken hold, and they have made industrial disease reportable, and as a result legislative enactments are meeting the varying demands as they arise.

Child labor is receiving its quota of attention. Its deleterious influence on the child's health and length of life is under scientific investigation. Many States have already enacted prohibitive legislation, and only within a short time a most radical suggestion has been offered by one of our law makers—Senator Beveridge of Indiana—namely, to have the United States prohibit the transportation of all goods made by child labor in interstate and foreign commerce, on the ground that such articles are not "legitimate articles of commerce"—and thus to wipe out this practice entirely. To offset this, however, David Heron found that in the Yorkshire, England, woolen mills before legislation prohibiting child labor was enacted, the families in that section were large and well kept, because children were assets, while now the size of the family is kept down, and the children neglected, because the mothers are compelled to take their places in the factories. Investigations conducted along the same lines in our Southern States, where child labor is common, seem to point, though not yet with any degree of certainty, in the same direction. This is a problem requiring the most searching investigation before any conclusions can be drawn.

Intemperate living in all its phases, and the strenuous life, are responsible for a large part of the modern abbreviation of life. Strenuous living is the result largely of a desire, in a short space of time, to accumulate enough to last throughout a long period of contemplated case. The first part of this endeavor usually succeeds, but the last part of it fails of accomplishment in the greatest number of instances because of the lack of any life to live, after the strenuous period. Temperance in living must be preached.

The work of conserving and prolonging the life is now fairly launched, yet it still lacks the active support of the public at large; and it is here that physicians can and must help by their propaganda—for it seems that the physician's sphere is slowly narrowing itself down to the field of preventive medicine. The value of such work can be brought home to the public only by demonstrating the money value of each life saved to the community and thus to each individual. Prof. Irving Fisher, of Yale, estimates each life at a money value of $1,700. Civilization means materialization—but in a broader sense.

Little by little life has been prolonged, disease is being overcome, and life is worth living. We have now reached the average grand old age of fifty. Who knows what is to be the limit?

THE MEDICAL ASPECT OF ABDOMINAL PTOSIS.

Of late, and especially during the past two years, the surgery of abdominal ptosis and the various conditions more or less frequently associated with it have attracted widespread attention. This is largely due to the fact that careful researches by numerous investigators have added distinctly to our knowledge, and now terms unknown before, such as "Jackson's membrane" and "Lane's kink," have become familiar as household words in the literature of the subject. Especially has the x ray, with the perfected technic at present available, been employed in abdominal examinations, and this has been of the greatest possible assistance in correcting former errors and elucidating many obscure conditions. Hence, there has resulted a period of the greatest activity among our surgeons, and what may really be designated as a new era in this department of their art has been inaugurated.

In the enthusiasm for operative procedure it
should not, however, be forgotten that the vast majority of the affections in question properly belong to the domain of medicine, rather than to that of surgery; the judicious use of suitable mechanical support, as well as exercises and other physical methods, being, of course, included in the medical treatment. It is not to be denied, naturally, that surgery also has a legitimate field here—that in a certain proportion of instances operative interference is absolutely essential; but it is to be feared that, by many, quite too much stress is at present laid upon the surgical aspect of the matter. At a recent meeting of the Medical Association of the Greater City of New York, in which there was a somewhat extensive discussion upon some of the relations and results of enteroptosis, one of the speakers, himself an abdominal surgeon of large experience, entered a protest against what he considered the unjustifiably surgical trend of the evening's proceedings. He expressed this opinion in most emphatic language, stating that he did not believe that one case in a thousand, or even as many as that, called for operative procedure. He was convinced that the very great majority of these patients could be satisfactorily treated without operation, and especially by means of mechanical support; though it was, of course, essential that such support should be of proper character and intelligently applied. He said he could not but think, however, that the present craze, as he termed it, for surgical interference was only a temporary matter; one which would run its course and pass away, like the promiscuous fixation of prolapsed kidneys which was in vogue a little while ago. It is but just to many of our ablest surgeons to say that (except, of course, in cases of special emergency) they do not advise surgical treatment until medical measures, after a systematic and exhaustive trial, have failed to afford relief.

The medical aspect of abdominal ptosis is well presented by Dr. N. W. Jones, of Portland, Oregon, in the Interstate Medical Journal for July. As Doctor Jones says, many different factors enter into the question of the response and outcome of enteroptotic patients to treatment; but when the asthenic child is more universally recognized, and its nutritional and physical needs properly attended to, there will be fewer adults who go through life presenting the varied symptoms of chronic intestinal stasis. He very rightly states that the success of treating general ptosis depends primarily upon the correction of this stasis. Consequently, it is of great importance to differentiate between those cases which can be successfully treated medically, those in which there are local forms of ptosis with irreleivable intestinal stasis, and which are distinctly surgical, and those cases of the latter character which present distinct complications of a medical character (such as secretional disturbances of the stomach) and after operation must be treated medically with as much care as the cases of the first group. A complete restoration of the prolapsed viscera may not be required in order to obtain good functional results; without this, the patient, under proper conditions, can often be made entirely well and strong. The success of the medical treatment of asthenic patients, and also many of those treated surgically, depends not only upon the relief of the stasis, but upon the patient's active and persistent cooperation: his willingness to learn the principles upon which his cure rests, and his perseverance with it long enough to insure the formation of body habit.

VACCINE THERAPY.

There is at present much discussion concerning the theory and the practice of vaccine therapy, or more correctly stated, bacterination. Much is said concerning stock and autogenous vaccines, and such questions as these are asked: Which shall be used? Can any benefit result from the stock variety? Shall the action of vaccines be controlled by the opsonic index, or, having determined that positive and negative phases exist, shall we trust entirely to clinical observation?

There can be no doubt that in many instances the introduction of bacterins has been followed by most favorable results. But now the question arises: Are the manifestations of infections due to the activities of a single organism or are they the result of the interaction of several bacteria? This seems to be the crux of the present controversy. There are those who contend that the use of a mixed bacterin, one composed of the dead bodies of a number of organisms, is equivalent to using a "shotgun" prescription in the hope that some one of the ingredients may hit the mark. The analogy does not seem to hold. We do know that there are many conditions in which the symptoms are the result of combined activities. Then, too, it is a very common occurrence to obtain several varieties of microorganisms when cultures are taken from infectious conditions. Shall autogenous vaccines of each be made and tried separately, waiting several weeks to determine the action or lack of action, or shall minimum doses of all be given at once, with the hope of getting more prompt reactions? If we wait for the individual reactions the patient will have had a splendid opportunity to become much worse. Inasmuch as there do exist mixed infections, it would seem that there is a place for mixed vaccines.
Changes of Address.—Dr. M. S. Kakels, to 35 East Sixty-first Street, New York, N. Y.

Pellagra in Los Angeles.—Four cases of pellagra were reported in Los Angeles by Senior Surgeon Brooks, of the United States Public Health Service, during the week ending August 2, 1913.

Sioux Valley Medical Association.—At the recent annual meeting of this association, the following officers were elected: President, Dr. E. D. Putnam, of Sioux Falls, S. Dak.; first vice-president, Dr. Robert Evans, of Fort Dodge, Iowa; second vice-president, Dr. J. M. O'Connell, of Fortuna, Neb.; treasurer, Dr. W. R. Brock, of Sheldon, Iowa.

American Radium.—It is announced that a company has been organized in Pittsburgh, Pa., for the purpose of developing the radium output in America. In our issue for June 21, 1913, we published an editorial article on the deposits of radium in the United States, and refer our readers to another item regarding American radium, which appears in this issue in our department of Miscellany.

An International Association of Orthopedic Surgery Planned.—At the meetings of the orthopedic section of the International Medical Congress, a committee was appointed for the establishment of an international association to further the progress of orthopedic surgery and to arrange for international meetings. Dr. Robert W. Lovett, of Boston, and D. Clarence Leslie Starr, of Toronto, are members of the committee.

New Contagious Disease Hospital to be Erected in Evanston, Ill.—Announcement is made that the $100,000 endowment fund for the proposed North Shore Contagious Disease Hospital has been raised, and the Evanston Hospital Association can now take advantage of the offer made by James A. Patten to build a hospital for contagious diseases, to cost $100,000, provided a like sum was raised by the city for an endowment fund. Plans have been prepared for the new building, and the work of construction will be started at once.

Kentucky State Medical Association.—Arrangements are completed for the annual meeting of this association, which will be held in Bowling Green on Tuesday, Wednesday, and Thursday, September 21, 22, and 23, under the presidency of Dr. David O. Hancock, of Henderson. Special efforts are being made to make this meeting one of the most successful ever held by the association. In addition to an excellent scientific programme, an elaborate programme of entertainments has been prepared by the local committees. An interesting feature of the meeting is the visiting physicians and their friends. Dr. Arthur T. McCormack, of Bowling Green, is secretary of the association.

St. John's Guild Sea Side Hospital to be Kept Open All the Year Round.—The board of trustees of St. John's Guild has decided to keep the Sea Side Hospital at New Dorp, Staten Island, open all the year round. Herefore the work of caring for sick children of the poor has been confined to the summer months, but the new buildings and equipment of the institution now make it possible also to care for convalescent mothers, who have been discharged from city hospitals, who will be able to build a hospital of its kind; and the hospital equipment consists of twenty buildings, including eight large wards and four solariums, an annex, the Lewis Memorial Cottage, an isolation building, and quarters for nurses and servants. This season 1,621 patients have been admitted to the hospital, with an average stay of 97 days.

The International Medical Congress.—The Seventeenth International Medical Congress was brought to a close in London on Tuesday, August 12th, and the delegates from all parts of the world who attended regarded it as one of the most successful to be held. During three weeks of the congress were awarded as follows: The Moscow Prize, to Professor Charles Richet, of Paris, for work on anaphylaxis; the Paris Prize, to Professor von Wassermann, for work on syphilis; the Hungarian Prize, to Professor A. E. Wright, of London, for work on anaphylaxis. Professor Friedrich von Muller, of Munich, was elected president of the Permanent Committee of the congress and also president of the Eighteenth International Congress, which will be held in Munich in 1917.

Changes in the Medical Department of Tulane University.—The medical department of Tulane University, hereafter to be called the Tulane College of Medicine, has been divided into four separate schools, with the following officers for each school: Throat, Ear, and Pharynx, Dr. Isadore Dyer, dean; the Post Graduate School, Dr. Charles Chassaing, dean; the School of Hygiene and Tropical Medicine, Dr. Creighton Wellman, dean, and the School of Dentistry, Dr. M. S. Kakel, dean. The following appointments have been made on the staff of the Post Graduate School: Dr. Henry Dickson Bruns, emeritus professor of ophthalmology, in the Post Graduate School, has been transferred to the active list; Dr. Creighton Wellman, dean of the School of Medicine, has been appointed professor of tropical diseases and preventive medicine; Dr. J. T. Halsey, elected professor of clinical therapeutics; Dr. C. C. Bass, elected professor of clinical microbiology; Dr. W. W. Butterworth, elected professor of pediatrics, and Dr. George S. Bel, professor of internal medicine.

Cerebrospinal Meningitis in New York City during 1912.—There has been but little cerebrospinal meningitis in New York city during the past two years. During 1912, 268 cases were reported, with a case fatality of 72 per cent, and a death rate in 10,000 of 0.36. The corresponding figures for 1911 were 314 cases, case fatality 74 per cent, and death rate 0.47. Outbreaks of this disease are not very frequent, and show remarkable periodicity, occurring about once every ten years. The last four outbreaks occurred in 1872, 1881, 1893, and 1904, the death rate for those years being 87, 4, 27, and 5.4 in 10,000 of the population, respectively. All of these years have been characterized by hard winters with much snow. In the year following each outbreak the death rate is above the average but was very low during the remaining intervening years. From 1872 until 1904, the interim death rate averaged 1.5 in 10,000 of population. Since the introduction of lumbar puncture, bacteriological diagnosis, and serum treatment the interim average has fallen below 1 in 10,000. This fall has been due as much to the exclusion of cases resulting from tuberculosis and other causes, as to the improvement in the result of treatment. These periodic outbreaks of cerebrospinal meningitis in our community of an accumulated number of susceptible individuals, just as occurs in the case of infantile paralysis. Judging by the past, a sharp increase in the prevalence of cerebrospinal meningitis during the next two or three years is at least as probable if meteorological conditions favor its development.

Personal.—Dr. Harvey Cushing, professor of clinical surgery, Harvard Medical School, Dr. William J. Mayo, of Rochester, Minn., Dr. John B. Murphy, of Chicago, and Dr. Lewis Thomas, of the Tulane University, have been elected members of the Western Reserve University, Cleveland, have been elected honorary fellows of the Royal College of Surgeons, London.

Dr. John A. Ferrell, has been appointed general manager of the hookworm research work of the Rockefeller institute, with headquarters in Washington, D. C.

Dr. Arthur D. Hirschfelder, associate professor of medicine in the Johns Hopkins Medical School, has been appointed professor of pharmacy and director of the pharmaceutical department of the University of Minnesota.

Dr. Adolph Schumacher, for two years first assistant on the medical staff of the University of Wisconsin, and in charge of the students' health, has resigned his position and gone to Chattanooga, Tenn., where he will engage in private practice.

Dr. Milton J. Rosenman, professor of preventive medicine and hygiene in the Harvard Medical School, has been awarded the American Medicine gold medal for 1913, for the most notable service to humanity during the past twelve months.

Dr. C. C. Price, of Scranton, has been appointed chief medical inspecter in the newly organized Department of Labor and Industry. Dr. W. H. Blakesley, of Philadelphia, has been appointed temporarily to the work of medical inspection, pending further organization of the department.

Dr. M. C. Stone, of Kansas City, Mo., has resigned as State bacteriologist.

Dr. Anna Dwyer, of Chicago, has been appointed a member of the Illinois State Charities Commission, to fill the vacancy caused by the recent resignation of Dr. John F. McCannally, of Carbondale.
A Contribution to the Conservative Surgery of the Heart.—Max von Arx reports the case of a man of thirty who received a stab wound of the right ventricle. The man had run about a quarter of a mile after receiving the injury before he lost consciousness from loss of blood. An hour later the pulse was only just perceptible, and the apex beat could hardly be felt. Tenderness over the region of the stomach and dullness on percussion to the left suggested a wound of the diaphragm and liver, but a thorough exploratory laparotomy failed to reveal any wound of the abdomen. The pleura was laid bare and found uninjured, and then the pericardium was exposed by the resection of the fifth and sixth costal cartilages, following the course of the knife. As soon as the stab wound in the pericardium was enlarged a large amount of thick, black blood escaped and the pulse grew stronger at once. A wound was seen in the right ventricle far to the right and under the sternum but, as the respiration was not good, no attempt was made to suture it. The pericardium was washed out with saline, a strip of gauze laid over the wound in the heart, the wounds in the pericardium and thorax were loosely tamponed and the skin sutured, leaving a small aperture. An infusion of saline was then given, and for a while the condition of the patient seemed to be desperate, but then he rallied. At the end of thirty-six hours the dressings were changed, after which the patient made a good recovery, the temperature never rising above normal, and the pulse ranging between 80 and 88. A year later it was found that the heart missed the normal counter pressure of the bony wall of the chest and had become dilated in consequence, so that the apex beat was slightly displaced. Such a consequence might have been avoided by an osteoplastic operation, if the condition of the patient had been such as to justify an attempt of this nature.

This case shows that it is not the hemorrhage alone that is dangerous in a stab wound of the heart, but that the chief danger is the compression of the heart by the blood poured forth into the pericardium. When this mechanical factor was obviated the direct danger to life was removed. The case also emphasizes the need of drainage of the pericardium, the same as of any other endothelial cavity, like the pleura or the peritoneum.

Verrucose Tuberculous Lesions of the Foot.—Nicolas, Montot, and Gravier report the case of a child in whom, a short time after a slight wound of the left foot had been sustained, there appeared locally lesions to which the authors applied the term "vegetative, sclerotic lupus," followed by enlargement of the cutaneous and inguinal lymphatic glands. A ganglionic mass could also be felt deep in the iliac fossa, clinically tuberculiform in nature. No signs of tuberculosis elsewhere could be found, and the condition was clearly a sequel to exogenous tuberculous infection of the foot. The authors protest against the benign prognosis usually attributed to verrucose tuberculosis, and advise complete and free excision of the area primarily involved.

Electrolytic Treatment of Rhinophyma.—H. Bordier reports excellent results in rhinophyma with electrolysis. Three parallel platino-iridium needles are introduced into one of the masses of redundant tissue—sebaceous adenoma with pachydermia—to be removed, the central needle being connected with the positive pole and the other two with the negative. In sensitive patients the region may be anesthetized with 0.5 c.c. of novocaine and epinephrin solution. The current is then turned on and progressively increased in strength until, if possible, forty milliamperes are reached. It should be continued until the tissues between the needles show a grayish color. The current is then gradually diminished and stopped, the needles withdrawn, and the foam produced carefully wiped off with cotton dipped in hydrogen dioxide or a mercury oxycyanide (one in 2,000) solution. The destroyed tissue blackens, shrivels, and becomes detached about two weeks after the sitting. Two lobes of the rhinophyma can be removed at one sitting. Where the growth is large and hangs in front of the nostrils the dependent mass is ablated at one sitting by passing the needles through its base twice, at right angles. Antiseptic local baths should be employed during the period of repair. Small elevations remaining after the electrolytic treatment are readily removed by diathermy, a fine metallic electrode being used. The nasal surface is then practically smooth, the cicatrical tissue flexible, and the color normal.

Differences of Rapidity of Gastric Evacuation as Indicated by Different Methods of Examination.—A. Martinet and L. Meninier state that they have been repeatedly struck by the contradictory information obtained from x-ray examination, clinical observation, and other methods of determining the rapidity of stomach evacuation. Thus in a patient subject to gastralgic attacks at long intervals, a bismuth meal was seen with the x rays to pass immediately into the intestine, indicating pyloric inconstancy and excessive motility, whereas, an Ewald test meal was evacuated only with normal rapidity, one third of the fluid administered remaining in the stomach one hour after.

The Carrying of Germs into the Tissues from the Skin by the Knife.—Alfred Steinegger states as an undoubted fact that a perfect absence of germs from the skin can be attained by no known method of disinfection, and that therefore it is to be expected that germs will be carried into the tissues by the knife. These germs he finds to be chiefly white staphylococci, with some lymphocytes and sarcine. He thinks it a good plan to change knives as soon as the incision has been made through the skin.

LYON MÉDICAL.

Electrolytic Treatment of Rhinophyma.—H. Bordier reports excellent results in rhinophyma with electrolysis. Three parallel platino-iridium needles are introduced into one of the masses of redundant tissue—sebaceous adenoma with pachydermia—to be removed, the central needle being connected with the positive pole and the other two with the negative. In sensitive patients the region may be anesthetized with 0.5 c.c. of novocaine and epinephrin solution. The current is then turned on and progressively increased in strength until, if possible, forty milliamperes are reached. It should be continued until the tissues between the needles show a grayish color. The current is then gradually diminished and stopped, the needles withdrawn, and the foam produced carefully wiped off with cotton dipped in hydrogen dioxide or a mercury oxycyanide (one in 2,000) solution. The destroyed tissue blackens, shrivels, and becomes detached about two weeks after the sitting. Two lobes of the rhinophyma can be removed at one sitting. Where the growth is large and hangs in front of the nostrils the dependent mass is ablated at one sitting by passing the needles through its base twice, at right angles. Antiseptic local baths should be employed during the period of repair. Small elevations remaining after the electrolytic treatment are readily removed by diathermy, a fine metallic electrode being used. The nasal surface is then practically smooth, the cicatrical tissue flexible, and the color normal.

 Differences of Rapidity of Gastric Evacuation as Indicated by Different Methods of Examination.—A. Martinet and L. Meninier state that they have been repeatedly struck by the contradictory information obtained from x-ray examination, clinical observation, and other methods of determining the rapidity of stomach evacuation. Thus in a patient subject to gastralgic attacks at long intervals, a bismuth meal was seen with the x rays to pass immediately into the intestine, indicating pyloric inconstancy and excessive motility, whereas, an Ewald test meal was evacuated only with normal rapidity, one third of the fluid administered remaining in the stomach one hour after.
the meal, together with twice this amount of secreted gastric juice. The amount of the meal remaining was ascertained by determining the amount of iron in it, ferrous sulphate in definite proportion having been added to the meal before its ingestion. The authors explain the rapid evacuation of the bismuth through the fact that, being devoid of the qualities of a food, it failed to excite the gastric secretory functions in a normal manner as did the appetizing Ewald test meal, and was not dealt with normally by the musculature. In view of these considerations, the author advises that, in testing the gastric motility, a meal be given first and the bismuth afterward, in order that the results may, in so far as possible, represent normal conditions of digestion.

**SEMAINE MEDICALE**

*Pleuropulmonary Fistulas Due to Artificial Pneumothorax.—I. Bard asserts that pleuropulmonary fistulas are caused far more frequently than is generally supposed in the production of artificial pneumothorax. They may be expected to occur in the majority of cases in which there are well marked adhesions. The danger attending such a complication is not sufficiently marked, however, to contraindicate artificial pneumothorax, especially in cases of tuberculosis running a rapid course and resisting ordinary methods of treatment. In fact, the immediate results of the formation of a fistula are rather more favorable than otherwise, the pneumothorax being more quickly completed and a more regular compression being insured. The ultimate consequences, however, are far from negligible and demand circumspection in the use of Forlanini's method in cases of medium severity, and even in fibrocaceous cases not of a very acute nature. Where a fistula does develop, an attempt should be made to keep the intrapleural pressure constantly high enough to overcome the pulmonary elasticity, in order that the fistula shall remain closed and heal as soon as possible. A fistula is present whenever the pressure of the gases in the pleural cavity is found, upon puncture, to be positive, i. e., greater than the atmospheric pressure, during both phases of quiet respirations. Such a positive pressure can be detected by dipping a glass tube connected with the needle into a vessel of water before the puncture and observing the changes in the level of the fluid in the tube when the needle enters the pleural cavity.*

**BRITISH MEDICAL JOURNAL.**

*Acute Endocarditis Following Gonorrhea.—A. Wilson Gill's patient, a healthy man of forty-four years, was attacked with a fatal endocarditis which appeared within two months after the onset of an acute gonorrhea. The acute gonorrhea responded to local treatment so well that a cure had been effected in a month. The gonorrheal endocarditis presented a picture quite typical of that of a very severe infections endocarditis of any other etiology. Gill is inclined to agree with the recently expressed view that gonorrhea is a more common cause of endocarditis than is usually supposed.*

**Spontaneous Reduction of a Dislocation of the Cervical Vertebrae.—William C. Bentall acted upon Horsley's dictum, "If the lesion is acute and in the cervical region, then certainly wait," and was rewarded by his patient's spontaneous return to health. The patient, a man sixty-five years old, received a direct injury which produced immediate paralysis from the neck down. X ray plates and careful examination, both physical and neurological, located the lesion at or just below the fifth cervical segment of the cord. The plate showed an increased interval between the third and fourth cervical vertebrae, and the lower edge of the body of the third was seen to have been pushed forward over the upper edge of the body of the fourth.*

**Dilatation of the Fallopian Tubes for Sterility.**—T. Hope Lewis, while performing an interval operation for appendicitis on a married woman who had been sterile, though married about six years, found the Fallopian tubes to be stenosed. These he dilated by means of probes and sounds clear up to the cornua of the uterus. Eighteen months later she was delivered of a healthy child. Lewis's case, however, was the sequel to a tubal operation performed the previous day, and had remained sterile after having had all of the usual operations performed for dilating the cervix and straightening the uterine canal. He suggested the dilatation of her tubes, which was readily agreed to, and on operation, found them structured at three or four points in each tube. Dilatation was very difficult, but was accomplished, and she was pregnant within a year. This patient was also the victim of severe pain during the middle of her intermenstrual period. This "middle pain" was absent after the dilatation of her Fallopian tubes. Lewis expresses the belief that there are many cases of obstinate sterility which might be relieved by this procedure of dilatation of the Fallopian tubes.*

**Pellagra in Great Britain.**—Louis W. Samson's recent discovery of several cases of pellagra in Great Britain, and his recent papers concerning its etiology, have led to his receiving information concerning three new indigenous British cases. In one of these he has personally confirmed the diagnosis and has visited the district in which the child had been brought up. There he found rapidly flowing streams in which he observed larvae and pupae of *Simulium*. Swarms of these flies were also encountered in the region. The second case is typical, but Samson has not yet seen it personally. The third he has. With regard to the British cases thus far reported, it may be noted that the symptoms are typical, but the disease seems highly fatal, and a relatively large proportion of children is attacked. Samson regards the disease as endemic in Great Britain and believes that there are hundreds of unrecognized cases. The reported British cases absolutely disprove, according to the author, the maize theory of the etiology of pellagra.

**Nodular Leucemia.**—Gordon R. Ward discusses what he terms the four "associated syndromes" of leucemia, namely: Chloroma, or the presence of symmetrical skull tumors, often, but not always, of a green color, leads to blindness, deafness, etc. There may also be similar lesions of the peristeme in other situations. That known as the "mucosis fungoides" syndrome is the sec-

spinal mumps, as mumps, in the same quarter of the town, and
eight of the total number got milk from a common dairy. It seems
that all twelve paratyphoid patients were infected from a common
source.

The Black (Pigmented) Appendix.—William
Battle records three cases in which the appendix,
when removed for appendicitis, was deeply pigmented. The color was "brown
bluish" and was usually so scattered as to give a mottled ap-
pearance, being less intense in some areas than
in others, though not absent. Microscopical exami-
nation showed the pigment deposited in the
mucous membrane, lying both in and between
the cells. Chemical analysis showed the pigment to be a
compound of iron, the precise nature of which could
not be determined owing to the scarcity of
material. The presence of iron in these three cases
agrees with the findings of Simon in other cases
of similar pigmentation. A feature common to all
three of Battle's cases was the previous chronicity
of appendicular symptoms.

An Analysis of Thirty-five Consecutive Cases
of Bradycardia.—C. E. Lea finds the relative inci-
dence of the several types of bradycardia, as en-
countered in his series of consecutive cases, to be
as follows: True bradycardia, in which the whole
heart is concerned, not the ventricles alone, was
present in seven cases, or twenty per cent. Missed
beat caused the condition in nine cases, or nearly
twenty-six per cent. Heart block gave rise to three
cases, or 8.5 per cent. Lastly, the bradycardia
resulting from the digitalis treatment of cases of
auricular fibrillation is by far the most frequently
encountered form, being present in sixteen cases,
or almost forty-six per cent. of the whole. It is worthy
of mention that all forms of bradycardia except
the first are in some way causally related to an altera-
tion in the function of the auriculoventricular con-
ducting mechanism.

Arsenic Cancer.—R. J. Pye-Smith reports a
case of this rare condition seen under the care of
W. H. Nutt and examined pathologically by J. M.
Beattie. The patient was twenty-nine years old,
female, and married. When first seen in Febru-
ary, 1910, she was complaining of an ulcer under
her wedding ring. This had begun eight months
previously as a slight thickening of the skin. After
breaking down into an ulcer it had resisted all forms of treatment. The finger was amputated in August of the same year and the ulcerated part was found to be epithelomatous. The wound failed to heal completely and soon ulcerated again, presenting an appearance similar to the original ulcer. She then called attention to a small ulcer of about seven months' duration, located in the hair of the pubis. Ulceration was also found on the labia. No improvement took place under antisyphilitic treatment, and examination of a piece taken from the pubic ulcer showed it to be epithelomatous. The past history of the patient brought out the fact that she had always had a dry skin; that from seven to fourteen years of age she had been under treatment for that condition and for a few scaly spots. Amputation of the hand and subsequent wide excision of the pubic ulcer gave much relief and freedom from local recurrence of the epithelomatus. Her scalp and various parts of her body showed a few dry, slightly raised red patches, covered with scales or crusts suggestive of seborrheic seica. On the upper extremities there were several spots like psoriasis. Scattered over the hands, forearms, and feet, sparsely on the trunk, were small lumps with a thick, hard epidermis, like warts or tori, some being red at their bases. For six months after her third operation—removal of the pubic ulcer—she remained well, but there began to develop pleuritic symptoms and she died ultimately from what seems to have been widespread visceral metastasis. No local recurrence occurred. Autopsy was not permitted. The cause of such an epithelomatous state was almost certainly the arsenic which she is believed to have taken continuously for over three years when a girl. There follows a summary of the thirty undoubted cases of arsenic cancer to be found in medical literature and a discussion of the disease as an entity will be taken up in the continuation of the article.

Contamination of the Thoracic Cavity and Its Contained Glands.—C. C. Twort experimented on a wide range of animals, but chiefly rats, mice, and rabbits, to determine the spread of living and dead, virulent and avirulent bacilli after their introduction into the peritoneal cavity. His findings are, in his own words:

The experiments that have been performed demonstrate that, although the peritoneal cavity is provided with an extensive protective mechanism, inoculated bacilli escape from this cavity and can be found living and virulent in the thoracic glands shortly after inoculation. The rapidity with which this transmission takes place is remarkable. The bacilli being found from two to five minutes later in the glands, and from these cultures may be easily obtained. The bacilli found at the end of five minutes are mostly free, but a few may be already within the cells, and as the interval between the inoculation and the death of the animal is extended the number of bacilli not only becomes progressively greater, but the proportion of intracellular to extracellular is relatively much higher than in the animals killed earlier. It is interesting to note that as early as five minutes after the inoculation of the animal cultures can also be obtained from the pleural fluid, but the possibility of contaminating the fluid during the manipulation by the severing of the lymphatic channels is evident. On examination soon after inoculation, of the cervical, submaxillary, axillary, and groin glands, no bacilli can be found. No bacilli were found microscopically in specimens made from the thoracic glands and pleural fluid of animals that were killed before making the intraperitoneal inoculation and an examination made five minutes later.

There does not appear to be much difference in the number of bacilli found in the mesenteric and thoracic glands in animals killed about the same time after inoculation, although usually bacilli are found more often in the thoracic than in the mesenteric glands. Living tubercle bacilli gradually become less in the mesenteric glands, while they remain numerous for months in the thoracic glands. Cultural experiments parallel the microscopic ones and are even more satisfactory. It is seen, from these and other experiments, that the place of predilection for the development of a bacillus often has little or no relation to the site of primary inoculation. By experiment Twort has also found that injection of oil into the peritoneal cavity does not prevent the escape of bacteria from the peritoneal cavity and their absorption by the thoracic glands. It is, therefore, doubtful whether this procedure, as practised by some surgeons to prevent infection during operation, has any value whatever. Twort concludes with the following practical deductions from his experiments:

The time necessary for the escape of infectious material from the peritoneal cavity is thus often only a question of minutes, and it is obvious that even during an operation if the general peritoneal cavity is accidentally contaminated from the rupture of a localized abscess; etc., ample time is given before the end of the operation for the thoracic glands to become infected; and if these glands are penetrated there is a danger of the infection becoming generalized. These facts may explain the beneficial effect of Fowler's position after abdominal operations.

The Decalcifying Action of Oxalic Acid.—H. J. B. Fry reports three cases of oxalic acid poisoning and suggests that many of the symptoms seen may be due to the reduction in the calcium content of the tissues by the precipitating action of the oxalic acid. Such symptoms are: Convulsions, twitchings, muscular weakness, fall of blood pressure, loss of tone of cardiac muscle, and disturbance of its functional capacity; changes in strength of the pulse due to an increased susceptibility of the vasomotor nerve endings to epinephrin, etc., bradycardia, neurotrophic states, skin eruptions, vomiting, and constipation. Fry supports his contention with evidence drawn from various sources to show the rôle of calcium and the effects of its reduction or increase. The natural corollary from his hypothesis is the necessity for the use of calcium salts in the treatment of oxalic acid poisoning.

JOURNAL OF LARYNGOLOGY, RHINOLOGY, AND OTOLOGY

Contribution to the Surgery of the Hypophysis.—Jules Broeckaert states that the surgery of the hypophysis cerebri is commanding the attention of the rhinologist because of the more easy approach to the pituitary body through the nose, entailing less mutilating operations than by the intracranial methods. Considerable difficulty may be encountered, however, because of the inconstancy of the anatomical relationship of the sella turcica and the sphenoidal sinuses. The fact that the septum dividing the two sinuses is seldom in the median line may be a source of considerable trouble. The sphen-
noid cavities may be approached by the palatine route, as proposed by König; or the endonasal route as suggested by Hirsch. West and Citelli have each suggested a method, somewhat similar in approach to that proposed by Hirsch, but entering at the side. Any deviation from the median line increases the danger of these operations because of the important structures in the neighborhood. The palatine route necessitates a central incision through the velum, the removal of the horizontal plate of the palate bones and posterior part of the septum. The sphenoidal sinus is then opened in the median line by destroying the bifurcated edge of the vomer and the crest of the sphenoid. The septum of the sinus is removed and the floor of the sella turcica attacked with a small chisel and an opening made to the extent of one centimetre. Hirsch advocates opening the superior osseous part of the nose like a double door by a "Y" shaped incision, of which the vertical part follows the dorsal line and the two oblique branches divide the nose below the nasal bones. A submucous resection of the whole nasal skeleton is then performed and the sphenoidal sinus and sella turcica opened with a gouge between the two blades of a strong speculum, which separates the two layers of the mucous membrane and crushes the lateral masses of the ethmoid. The author thinks that the submucous resection of Hirsch is long, tedious, and unnecessary, and thereby sacrifices the entire septum, except the columnar cartilage. This method leaves the turbinates and ethmoids intact as far as possible. Radiography should always determine if the anatomical dispositions will permit access to the hypophysis by the route proposed.

August 2, 1913.

Clinical Effects of "Natural" and "Synthetic" Sodium Salicylate.—A. W. Hewlett reports the results of a cooperative investigation undertaken by the Council on Pharmacy and Chemistry of the American Medical Association, which was participated in by twenty-seven clinicians of recognized standing; the reports from these embodying approximately 230 separate observations on the effect of the salicylate powders used. Allowing for statistical error (and it is stated that the statistical variations in the figures presented were surprisingly small), it must be concluded from this investigation that the natural and the synthetic sodium salicylates are indistinguishable so far as their therapeutic and toxic effects on patients are concerned.

Intracranial Division of the Auditory Nerve for Persistent Tinnitus, by C. H. Frazer.—See this JOURNAL for July 5, p. 47.

Mycosis Fungoides Following Psoriasis, by Howard Fox.—See this JOURNAL for July 5, p. 43.

The Technic of Röntgen Ray Examinations of the Gastrointestinal Tract, and the Interpretation of Screen and Plate Findings, by R. D. Carman.—See this JOURNAL for July 5, p. 39.

A Case of Lymphangiomatous Circumscription. — P. E. Bechet reports a case of this comparatively rare dermatosis, occurring in the service of Dr. J. Kingsbury at the New York Skin and Cancer Hospital. The patient is a girl of thirteen, and the disease began when she was three years old, first appearing as a reddish inflamed patch, on which vesicles shortly developed. The lesion slowly increased in size until four or five years ago, but since then has remained stationary. The patch is about four by five inches in diameter, of ovoid contour, and consists for the most part of pearly vesicles, though, in con-sequence of the rupture of capillaries and the admixture of blood with the lymph contents, some are of a deep red, purplish, or blackish color.

The Significance of Plasma Cells in the Tonsil. A Preliminary Report.—J. G. Wilson, having mentioned that in an article published last year he emphasized the significance of what he called the overfunctioning tonsil in childhood, states that the views expressed by Dr. D. J. Davis, in a recent article on The Tonsils in Childhood, appear to be somewhat at variance with what he had written. If, he says, Dr. Davis's conclusions are correct, and the opinion he expresses of the significance of plasma cells in the tonsil is true, we seem driven to the conclusion that the supporters of complete enucleation of the tonsil under all conditions have proved their contention that the tonsil is from the earliest stages of life a diseased organ, which it is our duty to remove. Furthermore, we must apparently admit that the tonsils are vestigial structures, and the author reiterates what he has frequently declared, that neither embryology nor comparative anatomy, nor yet physiology, gives any support to such a hypothesis. The opinion that they are vestigial in man, and even worse than useless, has done considerable damage and created prejudice against such an endeavor to discover their nature and function. Dr. Wilson sums up his position thus: Plasma cells are derived from lymphocytes and are engaged in removing and utilizing cell material which has broken down. If it be pathological to destroy albuminous bodies and toxines arising from katabolic processes and possibly also of bacterial origin, then plasma cells are pathological. They are not degenerated cells, but cells actively engaged in combating the toxines which pass through adenoid tissue. Their presence, instead of showing that the tonsil is diseased, indicates that it is functionally active. Their presence in excess shows that we have some focus of disease, but not necessarily a focal one.

MEDICAL RECORD
June 2, 1913.

Differentiation of the Erythema of Scarlet Fever and that of German Measles. Diagnosis. — S. D. Hubbard points out that while scarlet fever, with all of its classical cardinal symptoms—following in fairly regular sequence and prominence—is not ordinarily difficult to recognize, this regularity is the exception, rather than the rule. The distinctive characteristics of the two diseases he gives as follows:

SCARLET FEVER.
More or less severe constitutional symptoms.
Severity and intensity of fever.

GERMAN MEASLES.
Very slight constitutional symptoms.
Severity and intensity of
rash in direct proportion to constitutional manifestation.
Enlarged glands, usually following onset, and evidence of sepsis.
Glands swollen and tender.
Confuent scarlet (pink) rash.
Rash punctate.
Onset sudden and more or less severe.
Tongue, milk-coated; later (about third day) "strawberry."
Pulse, high tension and increased.
Circumoral pallor.
Vomiting.
Rash appears quickly, spreads rapidly, and disappears gradually.
Rash appears first on neck and about clavicular spaces.
Rash fades with yellowish shading, leaving skin more or less injected.
Desquamation in twelve to fourteen days.
Desquamation in sheets.
Squamous scales.
Has more or less severe sequela.
Itching more or less prominent.

Observations and Suggestions Regarding Lobar Pneumonia.—E. E. Cornwall states that the toxines which most commonly make trouble in pneumonia can be divided into three classes: The specific toxine, autotoxines, and pharmaceutical toxines. The specific toxine, derived from the pathogenic cocci in the blood, does not seem to be regularly a factor of grave pathological importance, though occasionally it may be so. The autotoxines, and particularly those of intestinal origin, constitute a very important element in the mixed toxemia of pneumonia. The pharmaceutical toxines are, of course, drugs given to the patient. The official alkaloids, drugs belonging to the coal tar, phenol, and salicylic acid groups, mercury, and magnesium sulphate, all of which are widely used in pneumonia, are familiar poisons, and even dangerous ones unless given with caution. When we put a drug with toxic possibilities into a patient with such a grave disease, in which a very small thing may suffice to turn the scale, we should be reasonably sure that the advantage will be greater than the injury. For pain, restlessness, and sleeplessness, especially early in the disease, no drugs are so efficacious, as well as safe, as the alkaloids of opium; later, they should be used with very great caution. The author makes the following suggestions regarding treatment: 1. Give the patient plenty of fresh, cold air, but after defervescence protect him carefully from being chilled. 2. Keep down the production of toxines in his intestines by means of a fluid antiputrefactive diet supplying daily not more than forty grammes of protein, with a food value of not more than 1,250 calories—much less, should abdominal symptoms appear. 3. Include in his diet sufficient quantities of the salts needed by the body, especially the calcium salts. 4. Do not delay too long the stimulation of the heart; regulate the amount of this by the capacity of the heart muscle to respond, as well as by the requirements of his circulation. 5. Do not move his bowels unnecessarily, and let the means used to move them be gentle.

Obsessions in Medicine.—It is the belief of Beverley Robinson that these exist to a greater extent to-day than heretofore, and two reasons which he assigns are, first, exaggerated specialization, and, second, an undue estimate of science, evanescent though it be, as opposed to empiricism, i.e., the experience of decades, not to say centuries. The obsessions which he especially deprecates are the following: 1. The exaggerated and widespread notion of the marked contagiousness of pulmonary tuberculosis. 2. The neglect, in this disease, of such drugs as creosote, the hypophosphites, and cod-liver oil in connection with hygienic methods of treatment. 3. Immediate operation for appendicitis. 4. The idea that little can be done to reduce the mortality of pneumonia. If, the author states, the tuberculous patient is put to bed as soon as threatened, and creosote inhalations started and other judicious medical treatment employed, he will recover, provided he is not already too much handicapped by previous disease, or by reason of great weakness or old age, or because the poison is very virulent.

Tumor of Omentum with Twist of Pedicle, Giving Symptoms of Appendicitis.—C. Legiard-Laura, who reports this case, says that in the literature of omental tumors he had not been able to find a single one recorded with twist of its pedicle. The patient was operated upon for appendicitis, as acute symptoms suggesting that affection developed after a friendly tussle with another man, in which his body was briskly rotated and strong contraction of the abdominal muscles occurred. The tumor, the only source of the blood supply of which apparently was its pedicle, was removed, and it proved to be a lipoma with a well developed fibrous capsule.

AMERICAN JOURNAL OF THE MEDICAL SCIENCES.
July, 1912.

The Occurrence of Ankle Clonus without Gross Disease of the Central Nervous System.—Wildor Tileston, having referred to the fact that for a long time ankle clonus passed as one of the most certain signs of organic disease of the central nervous system, points out what conditions may be accompanied by ankle clonus without other evidence suggestive of disease of the nervous system, presents some illustrative cases, including one in which the autopsy revealed slight microscopic changes in the medulla oblongata, and discusses the importance of clonus in diagnosis and prognosis. By ankle clonus he wishes to be understood the true ankle clonus in which, on continuous upward pressure being made on the sole of the foot, there is a series of rythmical oscillations in plantar flexion and extension, occurring with a frequency of from five to
seven in the second and continuing for a considerable period. In summing up, he gives the following conclusions: 1. Ankle clonus indistinguishable from the genuine may be found more or less frequently in a variety of conditions, without accompanying organic nervous disease. 2. These conditions are: (a) Acute infectious diseases, especially typhoid fever; (b) chronic infections associated with marked toxemia, especially advanced pulmonary tuberculosis; (c) uremia, before and during the acute seizure; (d) epilepsy, immediately after the convulsion; (e) intoxication from certain drugs, e.g., hyoscine, ether, and chloroform; (f) excessive fatigue; (g) exceptional instances of certain neuroses, viz., neurasthenia, hysteria, paralysis agitans; (h) psychoses in the stage of excitement; (i) chronic articular rheumatism. 3. With the exception of joint disease, a toxic action on the nervous system may be assumed in all these states as the underlying factor in the production of clonus. 4. In the case of articular rheumatism a constant spinal irritation from the inflamed joint tissues is the probable cause. 5. In two autopsies on cases of phthisis, with clonus, no change was found in the central nervous system. In the author's case, however, inflammatory exudate was demonstrated about the posterior septum of the bulb. 6. Clonus due to toxic states may usually be distinguished from that of organic nervous disease by the absence of spasticity and of other signs pointing to such disease, and particularly by the absence of the Babinski and Oppenheim toe signs. 7. An exception to this rule is encountered upon the use of hyoscine in medicinal doses and immediately after the epileptic attack; in both of which instances the Babinski and Oppenheim signs may be positive. 8. The occurrence of ankle clonus is of prognostic value in uremia, preceding at times the acute seizure. It usually disappears a few days before death; otherwise its disappearance generally indicates an improvement in the patient's condition. The author states that in the infectious diseases the appearance of ankle clonus certainly adds to the gravity of the prognosis, as it indicates a high degree of toxemia; though it does not preclude the possibility of recovery.

Myocardial Hydrothorax.—Anders states that of twenty-seven cases of hydrothorax due to heart lesions coming under his observation, no less than sixteen were apparently caused by myocardial disease. In thirteen of the sixteen the hydrothorax was wholly on the right side throughout. In speaking of the diagnosis of this condition he says that cases are often characterized by extreme latency, particularly during the earlier portion of their course. In all his cases, however, the signs and symptoms of chronic myocarditis, and in five those of chronic interstitial nephritis, were present. A careful physical examination of the entire thorax would enlighten the clinician, but this is often neglected because the hydrothorax which gives rise, in a measure at least, to the dyspnea and cough is unsuspected. The principal error in diagnosis, it seems to the author, is in the assumption that hydrothorax is not to be expected in cases of cardiac disease in which the signs of chronic valvulitis and external edema are absent. It is not uncommon, indeed, to meet with cases of myocardial insufficiency which closely simulate those of valvular disease, particularly mitral incompetency with evidence of a mild grade of stenosis. In chronic myocarditis, however, there is not obtainable a clear history of acute articular rheumatism, but commonly of one of the exciting factors that may produce secondary cardiac dilatation, such as physical or mental strain, an intercurrent febrile affection, and the like. The treatment of this form of hydrothorax must have the same objects in view as in the other varieties, and has reference to the removal of the exudate by tapping the chest and, so far as possible, of the causative condition by hygienic and medicinal means. It is futile, as a rule, to attempt to get rid of the exudate by the exhibition of digitalis and other cardiac stimulants without first withdrawing the fluid by aspiration, if it be considerable in amount. Rest, absolute and long continued, is a most valuable adjunct. The use of saline laxatives, to the point of rather active catharsis, proved of decided service in a few of his cases. In five instances a salt poor diet was employed with favorable effect. Reports of the sixteen cases were appended. While death is inevitable in by far the majority of instances, one of the patients had shown persistent good health for fifteen years, following repeated aspirations and the use of cardiac tonics and stimulants, and other measures; another, for a period of twenty months, and still others for shorter periods of time.

Congenital Atresia of the Duodenum.—A. L. McDonald reports a case of complete atresia, with loss of continuity, of the duodenum. At birth the child was apparently normal, but it vomited incessantly, became emaciated, and died in about four days. The day before its death a diagnosis of pyloric stenosis, with probable complete obstruction, was made, and a hopeless prognosis given. The number of recorded cases of this kind is by no means large, though no doubt, the author says, some are not reported, and many pass unrecognized in the absence of a post mortem examination. Much malformations are of interest: (1) As a clinical entity difficult of recognition and, as to prognosis, practically hopeless; (2) in their clinical and etiological relationship to spasm and conditions of partial obstruction; (3) the theoretic interest of the possible embryological factors. Defects may be found at any point in the gastrointestinal tract, but are more common (in the order of frequency) at the following sites: (1) Pylorus and duodenum; (2) rectum and anus; (3) ileocecal region; (4) attachment of Meckel's diverticulum; (5) flexures of the large intestine. The prognosis is bad in all cases of even relative obstruction, because of the difficulty of nourishing the infant, and is practically hopeless in complete atresia. Hypertrophic pyloric stenosis is well recognized, and there are several reports of its successful surgical treatment and a few of medical treatment; though in the latter the diagnosis must remain in doubt. Cases of complete obstruction or atresia are absolutely hopeless unless the continuity of the intestinal tract can be reestablished by surgical procedure. So far as the author knows, no such successful operation has been reported, though many have been attempted.
The Antitoxine Treatment of Tetanus.—E. E. W. Given urges that treatment be begun at the earliest possible moment by elimination from the body as much of the toxin as possible by free venesection and lumbar puncture, and the injection of huge doses of antitoxine by subcutaneous, intravenous, and intraspinal methods to neutralize the unabsorbed toxin circulating in the body, together with intraneural injections to reach and neutralize the toxin contained within the nerves. No limit should be placed on the amount of antitoxine to be injected, if obtainable, for it will surely neutralize all the unabsorbed toxin, and if this is neutralized and the bacilli have been removed by the surgeon so that no more toxin is formed to be thrown into the system for absorption, the body will be able to successfully combat the amount already combined with the nervous tissues. Supporting systemic treatment is indicated, together with highly nourishing food in liquid form given, if necessary, through a stomach tube, and sedative drugs are to be administered as indicated, the patient being treated in a darkened and quiet room.

Treatment of Fracture of the Olecranon and Compound Fracture of the Patella.—George deTarnowsky emphasizes the following points in treatment of the fractured olecranon: 1. Fractures of the olecranon are best treated by the open method. In simple fractures immediate intervention is indicated; in compound fractures it is preferable to wait until primary reaction has subsided. 2. It is not necessary to wire or suture through bone. The periosteum and tendon of the triceps are sufficiently strong to maintain the fragments in apposition, provided the triceps is not allowed to contract. Anteroposterior angle splints absolutely prevent contraction of the triceps. 3. The most religious asepsis must be observed during the operation. Mr. W. Arbuthnot Lane’s technic for bone plating being used as a standard. No antiseptic irritants must be used for irrigation or swabbing. 4. Immobilization must be maintained for four weeks before passive motions are allowed. As to fracture of the patella excellent results are obtained by him by observing the following routine: 1. An interval of five days is allowed to elapse between the day of the accident and the operative treatment. In all compound fractures in or near joints he believes the best interest of the patient are conserved by primary inactivity. Recently traumatized tissues offer much less resistance to infection than the normal, and by waiting for the primary reaction to subside we get better results. If infection of the wound occurs, one should wait even longer. 2. No wiring of fragments is allowed. As in fracture of the olecranon, sutures are ampul sufficient, provided muscle contraction is overcome by immobilization. 3. No active or passive motions are allowed for five weeks after suturing of the fragments.

ANNALS OF SURGERY.
June, 1913.

Lymphangioplasty: Handley’s Method.—Park er Sym’s finds that Handley’s operation, according to the literature, has been performed in twenty cases for branny arm, in seventeen cases for elephantiasis, in three cases of chronic edema of the leg, in three cases of solid edema of the face and eyelids, and in ten cases of ascites. The writer reports two failures by this method, one in a case of edema following cancer of the breast, and the other in ascites due to cirrhosis of the liver. The findings of the reported cases of lymphangioplasty in various conditions has been as follows: Branny arm, twenty cases, with nine successes and nine failures, and two cases with no report as to swelling; seventeen cases of elephantiasis, all failures: three cases of chronic edema of the leg (not elephantiasis), all failures; chronic edema of the face and eyelids, three successful cases; ten cases of ascites in which half were partial successes, and half total failures.

Gas Cysts of the Intestine.—Percy R. Turnure concludes from reported cases and from the examination of his own pathological specimen in which obliteration of the cysts can be seen in many areas, that the condition is self limiting with a tendency to spontaneous cure. Therefore, if the predisposing cause is treated, there is no indication for resection of the affected bowel or even an attempt at removal of the cysts. The chief characteristics of the lesions are: 1. Extensive gas cyst formation, for the most part situated outside of the longitudinal muscular coat; 2. characteristic appearances of the gas cysts and the cyst walls, in which the presence of an endothelial-like lining and giant cells is a feature; 3. occurrence of spaces or channels, some of which may be lymphatics, partly lined by endothelium and partly filled with giant cells, endothelial cells, and leucocytes; 4. evidences of dilatation of lymphatics and of the intercommunication of large lymphatic spaces, possibly cyst spaces with undoubted lymph channels; 5. absence of communication between cysts; 6. inflammatory and productive processes between the cysts and under the peritoneum, resulting in the formation of a connective tissue and fibromatous masses, leading to the obliteration of certain cysts and therefore to a kind of healing process; 7. absence of bacteria in most of the cysts (the bacteria present in some places are probably post mortem invaders); 8. the deposition of highly refractive needles in the interior of many of the cysts, causing a peculiar flattening of the cells belonging to the lining membrane, and the possible role of such crystalline matter in the production of some of the giant cells.

Suturing of the Kidney.—J. E. Moore and J. F. Corbett summarize their experiments as follows: Mattress sutures cause extensive destruction of the kidney substance. Silver wire with mattress sutures causes a variable amount of damage. Simple incision with over and over sutures does not produce serious lesion. The Serrefine method produces slight lesion. While this is not free from infarction, the only legacy left is a slight loss of parenchyma without other complication.

“Dumb-Bell” Kidney.—J. L. Herman and George Fetterolf describe a specimen which was found while attempting to remove a kidney through a lumbar incision, which they were unable to do. After complete exposure of the kidney through the left loin, the cause of the impossibility of delivery was found due to a congenital abnormality, the main feature of which was a continuity of the renal tissue
of one side with that of the other across the spinal column. This could be determined readily by means of a finger passed along the dorsal surface of the renal tissue. In freeing the kidney a large renal artery from the left common iliac to the left lower pole was torn away, under the supposition that they were dealing with the perirenal adhesion, an unlikely mistake in the living, in the presence of pulsation.

ARCHIVES OF INTERNAL MEDICINE.

July, 1912.

Effect of Temporary Occlusion of the Renal Circulation on Renal Function.—R. Fitz and L. G. Rowntree found that in rabbits and dogs with one kidney removed, the circulation of the other kidney may be clamped for as long as forty minutes with recovery; clamping for a longer time, however, causes death with signs of renal insufficiency. In the animals ultimately recovering, temporary disturbance in renal function is produced as shown by the presence of albumin and casts in the urine, a diminished phthalein output and a delayed lactose and iodide excretion. Acute or healed pathological changes are found in kidneys so treated. Except in extreme cases, no definite relation between the pathological and the functional disturbances produced is demonstrable by the functional tests used.

Pathological Changes in the Thyroid Gland in a Cretinistic Variety of Chondrodystrophia Foetalis.—Douglas Symmers and G. H. Wallace assert that there is a form of chondrodystrophia foetalis (achondroplasia) in which, in addition to changes in the osseous system, there occur modifications in the soft tissues, attributable to pathological defects in the thyroid gland, and consisting of thickening of the lips, cheeks, eyelids, the wings of the nostrils and the lobes of the ears, macroglossia, hypertrophic vulva and myxomatous transformation of the subcutaneous and certain deep connective tissues. All of these, when combined with the large head and froglike expression, the protuberant abdomen, prominent skin folds, and pudgy extremities, fulfill the essential requirements for the diagnosis of cretinism. The thyroid gland in such cases shows an extensive chronic productive inflammatory process eventuating in replacement of the colloid vesicles by an overgrowth of alveolar epithelium, or by an invasion and substitution in the alveoli of connective tissue from the interstitium, aided, in both instances, by compression from the outside by the contracting fibrous trabeculae.

Experimental Chronic Nephritis.—J. P. O'Hare was able to produce in rabbits chronic renal lesions closely simulating those of chronic interstitial nephritis in man, by means of combined injections of uranium nitrate and the colon bacillus.

Paratyphoid Fever.—C. J. Hunt states that paratyphoid fever occurs in four general types, viz.: That closely resembling typhoid fever; that closely resembling influenza of the abdominal type; that suggesting a general gastroenteric inflammation with nausea and vomiting, and often diagnosed as phenamine poisoning; and that closely resembling dysentery, likewise often diagnosed as phenamine poisoning and almost as frequently as "cholera morbus." During the course of four epidemics of typhoid fever studied by the author, including 509 cases, 117, or 22.0 per cent., presented atypical features. The agglutination reactions of the sera in these 117 cases gave the following results: Bacillus typhosus only, 46.5 per cent.; Bacillus paratyphosus A only, 7.7 per cent.; Bacillus paratyphosus B only, 40.2 per cent. The remaining six per cent. showed mixtures of the organisms already mentioned, sometimes with Bacillus paracoli in addition. That in fifty-nine of 509 cases, or 11.5 per cent., there should have been a negative Widal reaction, notwithstanding the presence of typhoidlike organisms, shows plainly the importance to the general practitioner of determining the reaction in negative cases with organisms of the paratyphoid group. The suggestion is also made by the author that a mixed vaccine may be of greater utility than one of Bacillus typhosus only.

Reticulated Erythrocytes.—O. H. P. Pepper and M. M. Peet state that of the intraerythrocytic phenomena demonstrated by "vital staining," reticulation is most important. This condition is an evidence of youth of the cell. Study of the literature leads to the belief that reticulated red cells show greater resistance to hemolytic agents than others. The experiments of the authors in rabbits, however, failed to demonstrate any constant difference in this respect.

Quantitative Estimation of Chlorides in the Urine.—Stanhope Bayne-Jones presents a comparative study of simplified methods available for this purpose, and concludes that the Strauss method is simple, rapid, and gives results sufficiently accurate for clinical purposes. It is directly applicable to both normal and albuminous urine. When modified by performance of the test in a graduated fifty c. c. cylinder, instead of the Strauss tube, it gives results more accurate than in its original form. The method is based on the precipitation of chlorides by silver nitrate and the titration of the excess of the latter by ammonium thiocyanate, an iron salt being used as an indicator.

July, 1912.

Eugenics in Its Relationship to the Welfare of the Public.—T. B. Futcher states that the study of eugenics in this country has been stimulated by a gradual realization of the enormous number of insane and other dependents who have become a public charge and by the enormous expense to which the people are put to provide for their maintenance. It is a well known fact that the birth rate among the feeble minded is very much higher than among normal persons. If we accept the view of the eugenists that mental defects, in their various types, are largely dependent upon inheritance of these defects from progenitors, what are the remedies they propose to lessen insanity, feeblemindedness, epilepsy, etc.? It is recommended that reproduction be prevented by a surgical operation which anesthetizes or sterilizes the male or female. These revolutionary procedures have met with much opposition from the standpoint of prejudice, but the
eugenists believe that, with the education of physicians and the public, this prejudice will be gradually overcome. Already eight States have passed laws which provide some form of sterilization of the feebleminded and certain other defective or criminal types, and it is more than probable that other States will do so. The second method is the segregation, throughout the reproductive period, of the feebleminded below a certain grade. One of the difficulties encountered would be that of taking care of such persons when they were known, and another, that of determining when the reproductive period ends in men. The expense of segregation would be enormous at first, as it is estimated that at present only about one tenth of the defectives are being cared for. It is for this reason that sterilization is more likely to appeal to the legislator than segregation. A third factor advocated for the lessening of feeblemindedness, as well as for the prevention of the spread of venereal disease, is that marriage shall not be permitted without the license being accompanied by a certificate from one or more physicians to the effect that the contracting parties are healthy in every respect. The only possible way in which a method of this kind could be made really effective would seem to be to have a special board of examiners, appointed by the health authorities, before whom all applicants for marriage should appear for examination; and such a regulation is not likely to be endorsed in the near future. Fourth, more thorough control of immigrants allowed entrance is also advocated; and undoubtedly there lies in this direction a potent means of lessening feeblemindedness in this country. The author maintains an open mind as to what measures should be adopted, but he is convinced that the investigations being made by the eugenic societies will prove of great value in the uplift of the human race. There is no question, he says, but that best results are going to be obtained by a judicious combination of both eugenics and euthenics. Those who are active in spreading the knowledge of eugenics recognize the importance of improving the environment of the feebleminded; but while this will help these individuals, it will not prevent them from reproducing their kind. The subject therefore becomes one of vital public interest, not only from the public health standpoint, but also from the financial one, since the taxpayer has to pay for the support of these unfortunate defectives and criminals in institutions for the feebleminded and in jails.

NEW YORK STATE JOURNAL OF MEDICINE.

July, 1913.

The Problem of Caring for the Defectives. — William T. Shanahan's paper presents a concise outline of the several varieties of defectiveness, together with a brief discussion of their more important etiological factors, so far as these are known. He speaks in some detail on the subject of sterilization of adult defectives, holding a strong brief in opposition to the generalization of such a practice. Such a treatment of the male defectives tends to develop such tendencies as the abuse of alcohol, stealing, making assaults, ordinary and sexual, destroying property, etc. The female is prone to become a prostitute, or to increase such a practice. Both are almost certain to harbor and spread venereal disease in a community. The only good accomplished by the measure is the prevention of the occurrence of defective offspring, and this can be equally well accomplished by segregation and proper community care, which have the further advantages of preventing all of the previously mentioned dire results of simple sterilization with subsequent release of the individual. The ideal method of segregation is the colony plan on the lines of a large village, with its self-contained amusements and occupations. The author does not believe that health certificates before marriage will accomplish much from a eugenic point of view. In many instances they may prevent the union of those venerably infected, but from the standpoint of heredity such health certificates cannot be of much value to the vast majority of mankind, for the reason that the facts concerning heredity are not generally available. Shanahan says of another much mooted question of the present day, "It is my opinion that proper control of the sexual instinct is not to be obtained by constant detailed harping on the subject in schools, which often results in developing in children morbid ideas regarding the subject, for intimate knowledge alone of such matters has never proved a means of preventing man from permitting his sexual instinct to control him, instead of his being its master." He believes that the inculcation of habits of self control, together with the understanding that continence is compatible with health, and the stimulation of interest in diverse matters, are the most potent factors in proper sex education.

SURGERY, GYNECOLOGY, AND OBSTETRICS.

June, 1913.

Anesthesia and Anoci Association.—George W. Crie employs the following technic in abdominal operations: 1. Excluding infancy, old age, and depressed vitality, be first administers, as an average, 1/6 grain of morpbin, and 1/160 grain of scopo- laneone hour before operation; 2, if local anes- thesis is employed, novocaine in 1/400 solution is used by progressive local infiltration; 3, if in- halation anesthesia is employed, nitrous oxide, alone or with ether added as required, is administered; 4, as soon as the patient is unconscious, infiltration, first of the skin and then of the subcutaneous tissue, with 1/400 solution of novocaine is made. In order to spread the novocaine, immediate local pressure with the hand is applied. Anesthesia is immediate. Incision through this anesthetized zone exposes the fascia. The fascia is then novocainized, subjected to pressure, and divided. This brings us to the remaining muscle or posterior sheath and to the peritoneum. These structures are then infiltrated with novocaine, subjected to pressure, and divided within the blocked zone. If blocking has been complete, upon opening the abdomen no increased intraabdominal pressure will be found, no tendency to expulsion of the intestines, and no muscular rigidity; 5, the peritoneum is everted and infiltrated with a one half per cent. solution of qui-
nine and urea hydrochloride, completely surrounding the line of proposed sutures, and momentary pressure supplied. This infiltration serves as a block, and as it lasts several days it should prevent or at least minimize the postoperative wound pain and the postoperative gas pains, and by so much minimize postoperative shock; 6, if there is no cancer or acute infection in the field of operation, the following regions may be blocked as completely and in the same manner as the abdominal wall, viz., the mesoappendix, the base of the gallbladder, the uterus, the broad and round ligaments, and any portion of the parietal peritoneum.

Inversion of the Uterus.—W. C. Jones reports a case and summarizes the treatment of the condition as follows: In all acute and in most chronic cases, manual reposition should be tried. In most of the former, if undertaken early, and in many of the latter, this procedure is successful. If it fail, repositors, etc., may be used, but only for a short time. If these are unsuccessful, one should resort at once to some operative method, the one of choice being colpophrectomy. This operation stands preeminent in the treatment of difficult cases of uterine inversion, on account of the facility of its performance, and its success in accomplishing the reduction of the inversion, and also because of the practically complete absence of mortality. The uterine incision should be made at first through the cervix only, and later be extended as far down into the corpus as necessary to accomplish reposition. In inversion due to tumor, the treatment is mostly that of the causative fibroid. After this is removed, if the uterus still remains, in about one third of the cases spontaneous replacement occurs, while in the other instances reposition is accomplished usually without difficulty by nonoperative methods.

Acute Dilatation of the Stomach and Its Treatment.—O. J. Borchgrevink emphasizes the marked relief the prone position gives the patient. The patient is laid prone in bed with one pillow under the pelvis and one under the chest and throat. He believes an energetic and continual evacuation by the stomach tube has become the principal resource of acute dilatation of the stomach, as nothing is more rational than to unload the overcharged and strongly oversecreting stomach, and it is obvious that the sooner and oftener this is done the more satisfactory is the result. Often, however, this is accomplished with difficulty. The greatly distended stomach is full of gas and fluid, and the latter will, when the patient is lying in bed, mould the thin and yielding stomach to the excavations of the posterior abdominal wall. To bring the tube under the surface of the fluid is, under these circumstances, not always easy. One has to try tubing with the patient lying in different positions. Elevation of the pelvis, for instance, is often necessary to drive the fluid higher up in the abdominal cavity. That one must also insert the tube much deeper than usual is evident. A correct and consistent tube treatment must, however, be supported in different ways. To this belong reasonable stimulation of the heart, and a compensation for the patient's enormous loss of fluid by giving intravenous, subcutaneous, or rectal infusions.

The Medical Association of the Greater City of New York.

Stated Meeting, Held April 21, 1913.

Dr. Anthony Bassler said that while the surgical standards of drainage and extirpation of pathological tissue served to good purpose generally throughout surgery, in the subject at hand more than these should be given consideration, because we were dealing with biology. It was not simply a matter of intestinal stasis. We must remember that the bowel might be matted into one mass
by chronic peritonitis, so that great interference with peristalsis must exist, and still intestinal toxemia not be present. Nor were cases of intestinal ulceration, and many of these of a chronic type, were not accompanied by toxemia. The matter of intestinal stasis, an important one in this connection, was far from being proved, and it should always be remembered in medicine that the coexistence of two phenomena does not prove that the one is dependent on the other.

Adhesions took place in the pia mater, pleura, pericardium, and joint cavities only because of infection with bacteria, and the same was true of the peritoneal cavity. We did not have to go as far back as the animal kingdom to find adhesions in the amniotic fluid of the colon. Lastly, his studies had suggested that the bacteriology of the intestinal canal in adhesion cases was never normal. There were several forms of anaerobes of the bacillus claudei alone responsible for adhesions, not to mention some few conditions of the brain abscess. MacNeal had isolated a new bacterium which was commonly present in the stools of cases where there were marked adhesions and which, when grown in culture and thrown into the intestinal canal of dogs, would produce pericolic adhesions. By the injection of splanchnotopy in a reduced form, it was possible to excite a reaction that might be ascribed to the action of the sympathetic plexus of the abdomen. This being about the same type of degeneration noted in some cases of myoma uteri. Thus he felt that a toxemia affected the neuromuscular structures of the stomach and intestines. However, several factors, such as the production of dilatation of localized or generalized character. The splanchnotopy, as he knew, were the inhibitory influences of the hollow viscera of the abdomen. Thus, with the toxemia persisting, degeneration took place in the sympathetic system of the stomach, and men became dependant on the nutrition of the abdomen as a whole. Adhesions might ensue, as the final result of the toxemia, plus bacterial extravasation.

Dr. J. MacNeal said that peritoneal adhesions were either fibrous or fibrous. The former were very temporary, and either disappeared or became organized into fibrous adhesions. The fibrous adhesion was produced by a general peritonitis or by a localized injury to the peritoneum. It was difficult to conceive of some fibrousized injury occurring as a result of the penetration of soluble bacterial toxins through an intact intestinal wall, and it would seem that the local injury was most frequently caused by a localized infection of the subserous tissue following an invasion of the peritoneum by a bacterial toxin. The injury to the serous coat brought about a precipitation of fibrin which served as a weak bond of union to some contiguous structure. If this fibrin union organized into fibrous tissue, a typical firm adhesion was the result. It was the latter type with which the physician and the surgeon had to deal. Such a fibrous adhesion was of the same order as a scar, and it might be impossible to arrive at any reliable conclusion as to the original etiological factors by the examination of such a scar. In order to study the etiology of peritoneal adhesions resort might best be had to experimental surgery, to ascertain the exact conditions which determined the production of adhesions and to distinguish them from the circumstances under which the formation of adhesions did not occur. A series of careful observations along this line had recently been reported by Adams in his Hunterian lecture before the Royal College of Surgeons (Lancet, March 8, 1912). He had been able to produce both infected and bacteria free adhesions in the peritoneal cavities of guinea-pigs and rabbits. Some of the adhesions were induced by destructive injury to the peritoneum, with gradual invasion by introduction of foreign bodies (such as cotton sponges and drainage tubes) into the peritoneal cavity. Often these adhesions would subsequently become infected by the penetration of bacteria from the intestine. Extravasated blood in the peritoneal cavity rarely caused adhesions unless it had become infected. Infection of the peritoneum, and especially the introduction of infected foreign bodies, proved to be a ready method of producing adhesions in animals. The adhesion, he said, was one of the structures which most readily became adherent to an area of injured peritoneum. This was in part due to its wide range of excursion, and in part to the rapidity of absorption of foreign material by the peritoneal structures, and that the adhesions were wholly passive, and depended upon the active movements of other structures, the most important of such movements being intestinal peristalsis.

Dr. Robert Coleman Semp said that the so-called attie of the abdomen he believed to be of great importance from a pathological standpoint, and it was Doctor Morris who first called our attention to the fact that the "spider web" adhesions emanating from the diseased gallbladder and involving the pylorus or upper duodenum, produced a condition which he termed the "organ of the abdomen," because it was from that organ: a condition simulating gastric ulcer with commencing pyloric stenosis. Briscoe, in the Lancet of October 30, 1909, had reported several instances of the ending together of the pelvic viscera by an exudate, resulting in tumor, which when cultured, proved to be caused by the colon bacillus. These bacilli were also found to be abundant in the urine. Schotmüller had observed in fifty cases, mostly in women suffering from pyelitis, the pyloric ring or factor. MacNeal, and much to the credit of the colon bacillus, although none of the bacilli were found locally. All were familiar with the fact that herpes occurred with pneumonia, and this was doubtless due to analogous toxicines. Turke, as he well remembered, had produced gastric ulcer. It was extremely significant that the gastric and duodenal ulcer were found with considerable frequency in association with gallbladder infection and chronic appendicitis, as such ulcers were undoubtedly the result of some embolic process. It was of great importance from a pathological standpoint, and it was Doctor Morris who first called our attention to the fact that the "spider web" adhesions emanating from the diseased gallbladder and involving the pylorus or upper duodenum, produced a condition which he termed the "organ of the abdomen," because it was from that organ: a condition simulating gastric ulcer with commencing pyloric stenosis. Briscoe, in the Lancet of October 30, 1909, had reported several instances of the ending together of the pelvic viscera by an exudate, resulting in tumor, which when cultured, proved to be caused by the colon bacillus. These bacilli were also found to be abundant in the urine. Schotmüller had observed in fifty cases, mostly in women suffering from pyelitis, the pyloric ring or factor. MacNeal, and much to the credit of the colon bacillus, although none of the bacilli were found locally. All were familiar with the fact that herpes occurred with pneumonia, and this was doubtless due to analogous toxicines. Turke, as he well remembered, had produced gastric ulcer. It was extremely significant that the gastric and duodenal ulcer were found with considerable frequency in association with gallbladder infection and chronic appendicitis, as such ulcers were undoubtedly the result of some embolic process.
short-circuiting the colon. As to the x-ray, he thought it would be a great advantage if all the radiographs in a case were taken by one man; so that we might have a set of plates compared.

Doctor Morris said that his experience had been like that of Doctor Sym's. There was recurrence of adhesions because the original cause to which they were due remained, a chronic toxic infection. For this reason he had given up operations, excepting for the relief of urgent symptoms. Worse adhesions sometimes formed than those previously existing. The logical conclusion was that it was better to remove the colon. This, however, was not possible in many localities more primitive surgeons were adopting a procedure which, while of little severity, was at the same time effective. The latter was a short-circuiting of the colon, an operation which had been so simplified that it took but little time and gave the advantage of incontinence. He was not able to prevent the reversal of peristalsis; this would prove all that could be desired in quite a large number of cases. Methods were at present being tried out by surgeons, with the intention of preventing this reversal of peristalsis which had a tendency to carry the bowel content back into the colon above the short-circuit gate.

Dr. A. Ernest Gallant said it seemed to him most unfortunate that the trend of the papers and discussion this evening was to be centered around the idea that an impression of such a character should emanate from the meeting. He was convinced that the vast majority of these patients could be satisfactorily treated by means of mechanical support, though it was, of course, essential that the attendant shock should be relieved intelligently. He did not believe that one case in a thousand, if ever as many as that, called for operation. This craze for surgical interference in such cases, he thought, was not only a temporary fad, which would run its course and pass away like the promissory fixation of loose kidneys in vogue a little while ago. In the doing away with that he was happy to say he had been a pioneer.

Reese Satterlee agreed with Doctor Sym's as to the need of greater uniformity in bismuth radiography of the gastrointestinal tract. The use of different amounts and kinds of foods and metals in a series of cases was misleading. In quite a large number of series of cases during the past two and a half years he had studied the intestinal tract by means of the bismuth x-ray, in regard to the matter of motility. Two leading points of interest were constipation and ptosis, with or without adhesions. For practical purposes, the one disadvantage was that abdominal support would often suffice, but operation was sometimes necessary. Of the operative procedures, colopexy had been attended with success in his hands. In twelve cases it had been done with some good results as to constipation, and three of the patients had been followed long enough to show that relief had been accomplished. This might be slow, as in one patient with an eight day constipation, in whose case, after eight months' unsuccessful medical treatment, colopexy eventually relieved the situation. He thought operation might also be effective in the case of adhesions, by drawing the bowel out of the pelvis, where infective processes were apt to spread over a crowded bowel. He was now trying another method of overcoming adhesions, namely, by immunizing by means of autogenous vaccines made from bacteria isolated from the feces. This had proved successful in one case of obstinate ulcerative colitis of ten years' standing, relieving the toxaemia. It seemed as if this method ought to have a promising future for the peritoneal infections.

**MEETING OF THE AMERICAN THERAPEUTIC SOCIETY.**

_Held at Washington, D. C., May 5 and 6, 1913._

(Concluded from page 302.)

**Newer Notes on the Subject of Peritoneal Adhesions.**

—Dr. Robert T. Morris, of New York, remarked that cobweb adhesions in the attic of the abdomen were insidious in character. Their formation was usually accompanied by the presence of the lungs were congested and the stomach. They were capable, however, of causing or less serious consequences, torsion, chronic constipation, etc. Several theories had been advanced to account for their origin. In many cases they were undoubtedly due to toxic influences. Bacteria penetrated the wall of the bowel, or a part of the intestinal serous membrane was shed, and the lymph that exuded gave rise to permanent adhesions. They were found most commonly at the hepatic and splenic flexures and in the regions of the cecum and sigmoid flexure. The question arose as to this explanation of adhesions, for many of them were found chiefly in these localities and not everywhere. It was because active peristalsis tended to prevent the organization of the lymph and to favor its absorption. In the past, peritoneal adhesions had been attributed to other causes, as elsewhere along the course of the bowel. In some cases there was also hyperplasia of connective tissue which might result in the formation of Jackson's membrane or of Lane's knick. It was like the formation of Dupuytren's contracture, which he thought is the result of new formations in the parenchyma. At first he thought that he was dealing with a distinct entity in these adhesions. When they were broken up, the patients were apparently better. But later, he realized that in many cases the more he did surgically the more adhesions there were. Surgery has undoubtedly had a place in the treatment of some cases, but as a rule the insidious cases were best treated by the physician.

Doctor Babcock said that the theory advanced by Doctor Sym's was not reasonable. As far as the author was aware, no one was able to understand or explain the formation of these adhesions and he would appreciate light on the subject. Sometimes he wondered whether there were not two kinds of them, one due to ordinary causes and the other in toxic causes. For many years he had made no remarks to cobweb adhesions; we were gradually getting away from the old type of postsurgical adhesions, and they were now but rarely seen. This indicated the great advance that had been made in surgical methods.

Doctor Morris agreed as to the passing of postsurgical adhesions. Less attention was now given to the toilet of the peritoneum and as a result there were fewer adhesions. In many cases harm had come from excessive treatment in this direction.

**The Dangers and Disadvantages of Spinal Anesthesia.**

—Dr. W. Wayne Babcock, of Philadelphia, compared the results of ether anesthesia with those of spinal anesthesia based upon between 4,000 and 5,000 injections. The accidents and untoward effects occasionally observed during or after spinal anesthesia were discussed in detail. The conclusions reached were as follows: Either for general use remained the standard anesthetic in spite of its many newer dangers. Adverse reactions and surgical abdominal support would often suffice, but operation was sometimes necessary. Of the operative procedures, colopexy had been attended with success in his hands. In twelve cases it had been done with some good results as to constipation, and three of the patients had been followed long enough to show that relief had been accomplished. This might be slow, as in one patient with an eight day constipation, in whose case, after eight months' unsuccessful medical treatment, colopexy eventually relieved the situation. He thought operation might also be effective in the case of adhesions, by drawing the bowel out of the pelvis, where infective processes were apt to spread over a crowded bowel. He was now trying another method of overcoming adhesions, namely, by immunizing by means of autogenous vaccines made from bacteria isolated from the feces. This had proved successful in one case of obstinate ulcerative colitis of ten years' standing, relieving the toxaemia. It seemed as if this method ought to have a promising future for the peritoneal infections.
be employed when other anesthetics were contraindicated. It was comparatively safe, but it should not be forgotten that untoward results might follow the use of any anesthetic. It caused a marked lowering of the pulse rate and blood pressure. This was due to the blocking out of the vegetative nervous system so beautifully described by Doctor Hemmeter. The higher vagus, however, was active and sent stimuli to the stomach and intestines and this explained the increased peristalsis and spontaneous evacuation of the bowels often noted in intraspinal anesthesia. Thus the condition was the reverse of that obtaining in the early stages of anesthesia by other methods, and patients with low blood pressure, and particularly those following from shock were not good subjects for the intraspinal method. The cases should be selected with such considerations in mind. If, however, the patient had no shock the intraspinal method tended to prevent its occurrence.

Prolonged-Precipitate Parturition Due to Disengagement of the Disproportionate Head.—Dr. A. Ernest Gallant, of New York, related a case to illustrate the condition in point. The delay was due to the disproportion between the size of the head and the inlet, so that the baby did not present. There was a tendency to head down either by pressure on the fundus or otherwise. One maneuver was to stand behind the woman with your arms around her and your hands upon the fundus and let her throw the weight of her body forward upon your hands. Another was to place one hand of the forceps and use it to press and guide the head downward. He exhibited a forceps that he had devised, with a combination English and French lock, designed to prevent unsober extraction. The forceps is described in full in cases such as he described was due to the small size of the head. He referred to babies weighing seven pounds or less.

Doctor Gompertz discussed the efficiency of various kinds of forceps. The maneuver described by Doctor Gallant for affording assistance in delayed labor appeared to have its counterpart among the lower animals. It had been noted that when toads were spawning, the males would enucleate the females for the lower abdomen with their legs and exert pressure, apparently with the object of aiding the expulsion of the spawn.

The following officers were chosen for the year 1913-14: President, Dr. Howard Van Rensselaer, of Albany; first vice-president, Dr. Robert T. Morris, of New York; second vice-president, Dr. G. M., of Los Angeles; third vice-president, Dr. I. Madison Taylor, of Philadelphia; secretary, Dr. Lewis H. Taylor, of Washington, D. C.; treasurer, Dr. A. Ernest Gallant, of New York.

Council: Dr. Frederic H. Gerrish, of Portland, Me.; Dr. John Blake White, of New York; Dr. Thomas E. Satterthwaite, of New York; Dr. Clarence John Blake, of Boston; Dr. Francis P. Morgan, of Washington, D. C.; Dr. D. Olin Leech, of Washington, D. C.; Dr. Noble F. Barnes, of Washington, D. C.; Dr. Edward D. Fisher, of New York; Dr. A. Ernest Gallant, of New York; Dr. J. Madison Taylor, of Philadelphia; Dr. James C. Wilson, of Philadelphia; Dr. Alexander D. Blackader, of Montreal; Dr. Reynold Web Wilcox, of New York; Dr. Spencer L. Dawes, of Albany; Dr. Lewis H. Taylor, of Washington, D. C.

Book Reviews.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

Radasch's compend is an exceptionally valuable one of its kind. Clear, concise, and practical, it is an excellent book for any worker in histology, he student or practitioner. The most important additions introduced in the present edition, besides introduction of a few new terms not introduced in the last edition under the same title, have been: A new chapter on the development of the placenta and the latest findings in the development of the embryo, considerable amplification of the subject of menstruation, and a rearrangement of the various parts of the nervous system.

TREATMENT OF ERYsipelas.

708 Waldheim Building, Kansas City, Mo., July 28, 1913.

To the Editor:

I have read with much interest the editorial on the treatment of erysipelas in your issue of July 20th. For the past fourteen years I have used Monsel's, locally or subcutaneously, one ounce to the pint of distilled water, or filtered rain water, using it as a cold compress. Internally I use saline laxatives and any of the peptones of iron preparation. There are severe complications of excited temperature and pain; in such conditions I use aconite for the fever and codeine sulphate for the pain.

A. M. WILSON, M. D.

THE BED BUG IN A NEW ROLE.

173 Lexington Avenue, New York City, August 4, 1913.

To the Editor:

Having read the editorial on this subject in your esteemed Journal of July 20th, I desire to call your attention to a letter published in your Journal of November 5, 1910, in which correspondence I spoke of the bed bug in a much more important rôle than the one you describe.

I quote from that communication of mine: "In a European city there lived a widow who supported herself by letting lodgings. A young mechanic rented a room from her, lived in it for a time, became sick with phthisis (tuberculosis), and died from this disease. Examination of the mattress, however, showed, that the occupant had likewise contracted phthisis and died from it. And so it happened with a third occupant of the fatal room. A physician who attended the last of these three persons, on hearing of the preceding cases, examined the room and found it infested with bedbugs. He made a microscopic examination of these vermin and found they were carriers of the bacillus of phthisis.

"We read much about the fly as a carrier of disease germs, but very little is heard of the bedbug, this dangerous insect. For the presence of this syphrophagous, as well as of other companion, the louse, there must be a raison d'être. It indicates unsanitary conditions, and the extermination of these insects is a most important matter, especially in houses, where there is a high percentage of contagious or infectious diseases. The ordinary general disinfection will not reach these foes."

Studying the history of the oldest popular disease, consumption, which the ancient East Indians called the king of diseases, I found that the danger of these bedbugs as carriers of the infection has been well understood by the Italian physicians of the eighteenth century, as we learn from an ordination of the board of health of Naples dated July 10, 1725. I shall give the translation of this ordinance in a paper on the history of phthisis which will appear within a few weeks. But even in Spain a similar edict had been given out under Ferdinand VI in the year 1751, of which latter edict, however, I cannot give the full text until I have completed my researches.

I may be permitted to close this correspondence with the same words with which I closed my letter of November 5, 1910:

"All these things, which I have brought before the profession from time to time through medical journals, as well as by means of a special circular addressed to the great Phthisiasis Congress at Washington, have been overlooked, and for this reason I beg to present my ideas before the board of health, the great, the quoad substantia of which the medical profession has a right to be proud.

A. ROSE, M. D.
Doctor Petty has produced an excellent book, dealing in a practical, thorough fashion with a most difficult group of phenomena. Obviously he has had a large experience and dealt successfully with the matters covered, as shown by his concrete and clear presentation. His views on the concrete problems are clearly defined, based on a multitude of observations and a shrewd common sense. In his interpretation of the causal factors of narcoticism he rejects the idea of neural or endocrine changes and holds the theory that the condition is essentially a toxemia belonging to the field of internal medicine; that "every symptom attendant upon the use or disuse of a narcotic drug is the direct outcome of drug, auto and intestinal toxemia." Just in proportion as the toxic conditions of the system are overcome, all these nervous and physical manifestations disappear. It is the belief of the author that "a drug patient could be made cell clean, that is, if every cell and structure of the body could be entirely freed from toxic matter, there would be no nervous manifestations or suffering incident to or following the withdrawal of narcotics from an habitue." His method consists in a thorough elimination of all the sundry poisons, selfmade or swallowed; the organs of secretion and excretion must be roused from the lethargy induced by narcoticism, and forced to work in normal or to the surcharged system is freed from toxicities. Much attention is given to the "physiologically balanced purge"; veratrum, and a gentler herb is recommended. Along with this is an ample consideration of tonic measures, activities, and other collateral rational agencies, including physical training as well as mind control. The evidence clearly indicates that a condition of intense intoxication with profound anemia is attended by derangement of the nervous system and impaired mentality. "The powers of perception are materially blunted, and actions based on perception may not represent the real intention of the individual, because erroneous conclusions are easily drawn from these impressions; actions based upon such conclusions would be correspondingly erroneous or untrue to the real intent of the individual." Again, the engorged condition of the portal system is the chief factor in bringing about a labored and deficient heart action, and this deficient heart action is an essential factor upon which collapse, the principle dangerous symptom, depends. If this engorged condition is remedied, then the other conditions developing out of it, if they occur, will have been effectively prevented by the previous treatment. "propositions as to the pathology and treatment of narcotic addictions, none of which had prior (to his presentation) been advanced." This book can be commended to the careful perusal of clinicians, who will learn from it much that is both original and useful.

This little book, while presenting nothing new, is an attempt to interpret the results of the various cardiologists, MacKenzie, Wenckebach, Lewis, and others, coupled with careful clinical observation; and as this is possible, a rational prognosis may be given in cases of dis eased heart. The author admits the difficulty, indeed, distinctly states his agreement with those who look upon prognosis of heart disease as a science. In the arrangements of the book, under matters of this nature, the matter is taken up, on page 32, in a rather abrupt manner, under the heading of, The Treatment for Mitral Regurgitation. This is doubtless merely a little oversight. In the section on the treatment of mitral stenosis, the writer speaks fully of the possibility of confounding functional and organic mitral regurgitations. Then he says, "Whereas in the case of mitral stenosis with the possible exception of Flint's murmur, there is never any doubt as to the structural char

acter of the lesion." This might have been qualified, with advantage, with the further statement that in the case of the Flint murmur of aortic regurgitation the left ventricle is always greatly hypertrophied and the apex correspondingly displaced, while in uncomplicated mitral stenosis this is almost never the case. Rarely, as Sir Isambard Owen has shown, in parallel with the engorgement of the left ventricle, is there a transverse position. Again, in speaking of tricuspid stenosis and the difficulty of diagnosticating this lesion, he fails to mention Macklin's diagnosis of a cardiac diastolic murmur and does not mention the obstruction of the vena azygos as the cause of hydrothorax, overlooking the methods of Dr. George Fetterolf, that the hydrothorax is induced by pressure of the dilated auricle against the pulmonary veins. By this, the book is a very practical one, however, thoroughly repays perusal, and can be especially recommended for its wise counsel along therapeutic lines. The writer places due importance upon rest and non-drug measures, relegating drugs to their proper position, that is as aids only when other rational measures fail. Through recognizing the value of digitalis, he is inclined to prescribe it only when indubitable evidence of failing compensation is present. Unfortunately, with many, digitalis is used almost as part of the diet.

The author has succeeded admirably in this volume in presenting clearly the salient points. It is not an extensive discussion of these large and important subjects, but the ground has been well covered; the various chapters taking up the hygiene of habits, foods, and food supplies, of schools and school children, occupations, municipalities, and of the person. The book can be recommended very highly.

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service, for the seven days ending August 6, 1913:

in Washington, D. C. Detail for the board: Surgeon Joseph Goldberger, chairman; Passed Assistant Surgeon J. P. Leake, recorder.

Army Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Army for the week ending August 9, 1913.

Anderson, J. B., First Lieutenant, Medical Reserve Corps. Ordered to active duty and will proceed to Fort Monroe, Va., for duty. Bevans, James L., Major, Medical Corps. Requisitioned unexpired portion of leave of absence and reported for duty at Headquarters, Westover Field, on July 28th. Bingham, Ernest G., Captain, Medical Corps. Leave of absence extended one month. Boyer, P. L., Major, Medical Corps. Left Madison Barracks, N. Y., on August 1st, for Glen Falls, N. Y. Bruns, E. H., Captain, Medical Corps. Granted leave of absence for one month about August 2, 1913, with permission to apply for an extension of two months. Carswell, R. L., Captain, Medical Corps. Granted four months' leave of absence upon relief from duty in the Philippines, with permission to return home via New York and Philadelphia. Charles, R. W., Captain, Medical Corps. Relieved from duty as assistant to the curator of the Army Medical Museum, and assistant instructor in clinical microscopy and bacteriology, Army Medical School, effective on or about October 1, 1913, and will proceed to Fort Logan, Colo., for duty. Edward, B. J., Major, Medical Corps. Ordered to Boise, Idaho, August 17 to 26, 1913, on militia duty. Gregory, J. C., Captain, Medical Corps. Granted leave of absence for travel with report by telegraph to the Adjutant General of the Army: is relieved from duty in the Medical Reserve Corps, effective on the expiration of four months' leave of absence, granted in orders of August 8th. Kilbourne, E. D., Captain, Medical Corps. Leave heretofore granted extended one month. Maus, L. M., Colonel, Medical Corps. Granted six days' leave of absence, about August 11th. Mitchie, H. C., First Lieutenant, Medical Corps. Left Texas City, Texas, on July 29th, en route to Walter Reed General Hospital for observation and treatment. Miller, R. B., Major, Medical Corps. Left Texas City, Texas, on July 21st, en route to Fort Wayne. Phalen, J. M., Major, Medical Corps. Assigned to duty as sanitary inspector, Southern Relief, relieving Major R. E. Miller. Reno, W. W., Major, Medical Corps. Left Gettysburg, Pa., on August 1st, with Field Hospital No. 1, en route to Camp Perry, Ohio. Richard, Charles, Colonel, Medical Corps. Left Army Medical School on August 6th, on fifteen days' leave of absence. Sparrenberger, F. H., First Lieutenant, Medical Reserve Corps. Left Leck- mann General Hospital, July 29th, en route to Fort Bayard General Hospital for observation and treatment. Thode, E. F., First Lieutenant, Medical Reserve Corps. Ordered to duty in Fort Groble, R. 1., August 4th, for duty until the arrival of another medical officer at that post. Turnbull, S. J., First Lieutenant, Medical Corps. Ordered to temporary duty with the Second Battalion on Fort Salute, Tex., City. Waring, J. B. H., First Lieutenant, Medical Corps. Furlough leave on August 1st, to Walter Reed General Hospital for observation and treatment. Woodward, Julius H., First Lieutenant, Medical Reserve Corps. Resignation of his commission from the Medical Reserve Corps has been accepted by the President, to take effect August 2, 1913.

Navy Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Navy, for the week ending August 9, 1913.

Births, Marriages, and Deaths.

BORN.

Walker.—In Philadelphia, on Monday, August 4th, to Dr. and Mrs. Le Roy Augustus Wilkes, a son.

Married.

Kauffman—Keenan.—In Philadelphia, on Wednesday, August 6th, Dr. Louis G. Kauffman and Miss Helen H. Keenan, both of Philadelphia. McNally—Sanaman.—In New Orleans, on Saturday, August 2d, Dr. Allan McNally and Miss Ida L. Sanaman.

Died.

Allen.—In Brooklyn, N. Y., on Sunday, August 10th, Dr. Emma F. Allen, aged sixty-eight years. Bailey.—In Philadelphia, on Friday, August 1st, Dr. Thomas W. Bailey, aged thirty-four years. Bigger.—In Los Angeles, Cal., on Sunday, July 27th, Dr. R. H. Bigger. Boyer.—In Washington, D. C., on Thursday, July 31st, Dr. Samuel S. Boyer. Carter.—In Gerrardstown, Md., on Saturday, August 2d, Dr. J. Pendleton Carter, aged eighty-seven years. Darby.—In New York, on Friday, July 25th, Dr. William J. Darby. Dennis.—In Oil City, Pa., on Friday, August 1st, Dr. Bernard Francis Dennis, of Buffalo, N. Y., aged thirty-six years. Hodson.—In Evansville, Ind., on Wednesday, July 30th, Dr. George P. Hodson, aged forty years. Hyder.—In New York, on August 3d, Dr. O. A. Hyde, aged sixty-one years. Ingles.—In Larned, Kans., on Sunday, July 27th, Dr. J. B. Ingles, aged sixty-five years. Jones.—In Oswego, N. Y., on Wednesday, July 30th, Dr. L. I. Jones, aged eighty-one years. Klostermann.—In Okawville, Ill., on Sunday, July 13th, Dr. Julius E. Klostermann, aged ninety-six years. Lane.—In Pawtucket, R. I., on Thursday, July 31st, Dr. Edward Monroe Lane, aged forty-six years. Leusmann.—In Chicago, on Saturday, August 2d, Dr. J. G. Leusmann, aged sixty years. Mackie.—In Boston, on Friday, August 8th, Dr. William B. Mackie. Manaton.—In Greenport, N. Y., on Wednesday, August 6th, Dr. William Manaton, aged forty-eight years. In Frederick, Md., on Monday, August 4th, Dr. Sellers Maynard, aged seventy-eight years. Moeller.—In Alhambra, Cal., on Sunday, July 27th, Dr. Adolph Moeller, of Milwaukee. Morrison.—In Martinsburg, W. Va., on Saturday, July 26th, Dr. George Porterfield Morrison, aged fifty-nine years. Nevers.—In Houlton, Me., on Monday, August 4th, Dr. Frank A. Nevers. Noble.—In Groton, Conn., on Sunday, August 3d, Dr. E. H. Noble, aged seventy-four years. Peiser.—In Carlinburg, Conn., on Tuesday, August 5th, Dr. Julius Peiser, of New York, aged fifty-four years. Richards.—In Wyomissing, Pa., on Saturday, August 2d, Dr. Emma Richards, aged sixty-three years. Saulsbury.—In Farm- hurst, Del., on Thursday, July 31st, Dr. George Porterfield Saulsbury, aged sixty-three years. Schoiz.—In St. Louis, Mo., on Thursday, July 31st, Dr. Philip Schoiz, aged seventy-one years. Todd.—In Chicago, on Wednesday, August 6th, Dr. Frank M. Todd, aged ninety-two years. Van Derveer.—In Whitehouse, N. J., on Tuesday, July 29th, Dr. James D. Van Derveer, aged seventy-five years. Whiteford.—In Pitkins, Md., on Saturday, August 2d, Dr. Lingard J. Whiteford, of Fullerton, aged thirty-five years. Waddell.—In Shelburne Falls, Mass., on Tuesday, August 5th, Dr. Andrew E. Waddell, aged eighty years. Wunder.—In Sabillasville, Md., on Sunday, July 20th, Dr. Joseph C. Wunder, of Balti- more.
Original Communications.

TOPOGRAPHY OF THE BLADDER, WITH SPECIAL REFERENCE TO CYSTOSCOPY.

(Illustrated With Case Reports),

By Victor Cox Pedersen, A. M., M. D., New York.

At the annual meeting of the American Urological Association, held in Boston, April 15, 16, and 17, 1913. Dr. Bransford Lewis read a paper entitled, "Where Is the Fundus of the Bladder?" In this he pointed out by direct quotations the fact that many observers and operators are loose, indefinite, and inaccurate in their use of this term. Thus it is that some case reports refer to the apical zone of the bladder as the fundus, others to the posterior part of the floor, fundus, or base, and so on, with more or less confusion, unless the reader is very careful to realize that a given writer has departed from the anatomical subdivision of the viscus into fundus, apex, and sides.

This exposition caused the writer to think that it might be well for urologists to adopt a nomenclature for the portions of the bladder of importance in cystoscopy. It is well known that the most important portion of the bladder includes the ureters, trigonum, and neck; consequently, any system of apportioning the organ should make one part include as much of these three anatomical features as possible. Another desideratum is to include the urethra, for the reason that in modern urology a full diagnosis cannot be reached without exploration with the urethroscope in both men and women.

A scheme of diagrams for the bladder and urethra is set forth in Figure 1, and the writer would add that he has found it of great service in his own work and would recommend it to his colleagues for adoption. The parts are obtained by the following procedure: The body is in the anatomical position, and a transverse horizontal plane is imagined as passing through the bladder just posterior to the point at which the ureteric folds disappear into the bladder wall. Such an imaginary plane will divide the bladder into superior and inferior halves. An imaginary vertical plane is passed through the bladder and the urethra throughout its entire length, thus dividing the bladder and the urethra into anterior and posterior halves. The two planes thus set off four quadrants of the organ.

Let us now consider the appropriate names of these portions thus outlined and their contents. Each of the subdivisions is broadly speaking a quadrant of the bladder. They might be conveniently denoted as follows:

First, the posterior lower quadrant, or, better, the ureterotrigonal quadrant, containing the right ureter and its fold, the interureteric fold, the left ureter and its fold, the trigonum, and the posterior half of the neck.

Second, the posterior upper quadrant, or by choice the subperitoneal quadrant, which lies beyond the ureteric and interureteric folds, and is not infrequently called the deep base or deep fundus of the bladder.

Third, the anterior upper quadrant, or preferably the urachal quadrant, inasmuch as this contains the true apex of the bladder with the remnants of the implantation of the fetal structure, the urachus. This quadrant might also be well known as the apical zone.

Fourth, the anterior lower quadrant, which might suitably be noted as the retropubic, inasmuch as it lies immediately behind the symphysis pubis and contains the anterior half of the neck of the bladder.

The importance of the neck of the bladder, and the fact that it is best explored with the retrovision telescope, or with the urethroscope, might be regarded by many as reasons for making it a fifth subdivision for office records and the like.

It will be noted that this classification groups the important anatomical parts of the bladder, and the chief zones in which pathological processes are common, in such a way as to be agreeable to, and consonant with, both these departments of medicine. It will be observed that Figure 1 displays these four sections of the bladder very successfully for diagrammatic record and reference, viz., the left hand figure shows the ureterotrigonal and the subperitoneal quadrants, while the right hand figure shows the urachal and the retropubic zones, and the neck is equally divided between the left and the right hand pictures.

For urethroscopy the transverse vertical plane of the bladder is made to pass vertically through the urethra, dividing it into anterior and posterior halves, which respectively correspond with the dorsal and ventral surfaces of this passage. If we enumerate the anatomical features in each of these portions in the male, the ventral will show from behind forward the vesical neck with the sphincter muscle; the prostatic urethra, one and a quarter inches long, containing the crest, colliculus, right and left prostatic sinuses, right, left, and middle prostatic ducts, sinus seminalis, right and left ejaculatory ducts; the membranous urethra, a quar-
ter inch long, showing chiefly the folds of the mucosa over the compressor urethrae muscle; the penile urethra, six inches long, containing the bulb, with Cowper's ducts, mucous glands, and the fossa navicularis. The dorsal portion of the urethra shows the prostatic ducts, folds of the membranous urethra over the compressor muscle, numerous mucous glands, the lacuna magna, and the fossa navicularis. Thus, it is relatively sparse in anatomic features, but very frequently the reverse in pathological conditions.

In the female the same plane of the bladder divides the urethra in much the same way, but the anatomic features are usually those of folds and glands only.

Another advantage of this system of dividing the bladder and urethra is exemplified in a plan of doing a cystoscopy which the writer always follows, and has found it to be at once thorough, orderly, and satisfactory. Inasmuch as the floor of the bladder, including the ureters and the trigonum, viz., the ureterotriginal quadrant, is in a certain sense the most important part, it should receive first attention before the medium changes or perhaps the eye of the operator tires. The steps of the procedure are as follows:

1. The air bubble at the apex of the bladder is at once located and regarded as in most cases marking the highest point and the middle line.
2. The instrument is then rotated to the patient's right, through 180 degrees to the base of the bladder in the middle line. It is then slowly withdrawn until the posterior border of the red trigonum is recognized distinctly set off from the paler portion of the base behind it.
3. The interureteric bar (plica interureterica) is next distinguished.
4. The instrument is now rotated to the patient's right along the plica, if present, or, if absent, along the red border of the trigonum until the right ureteric mouth is reached. The arc of rotation varies from 30 to 60 degrees from the middle point, according to the proximity of the ureters to each other.
5. The left ureteric mouth is located in the same way by rotation in the opposite direction, 30 to 60 degrees from the middle line, or 60 to 120 degrees from the right ureter.
6. After both ureteric mouths have been studied, the instrument is withdrawn about three cm., or the diameter of a focal field, and swept through an arc of 180 degrees from left to right, thus covering a "field zone" of the trigonum immediately in front of the ureters.
7. From this position at the right it is again withdrawn three cm., or until the neck of the bladder begins to interfere with the field, and then swept 180 degrees to the left. Usually one field zone will cover the trigonum, but exceptionally this plan of zone by zone procedure is necessary. These several manipulations serve to study the ureters, the trigonum, and the lower posterior quadrant of the bladder in a very complete manner, if the bladder is regarded as subdivided into anterior and posterior halves by the transverse plane passing through the neck and urethral outlet, as the patient stands in the anatomical position.
8. The instrument is now advanced to the interureteric bar again in the middle line as the chief landmark, and next three cm. (the diameter of a focal field) beyond it. From this point it is rotated 90 degrees to the patient's right, and next 180 degrees to the left; thus covering a field zone just above the ureters.
9. At this moment it is advanced another three cm., and rotated 180 degrees toward the patient's right. If more of the floor remains to be inspected, the same manner of procedure is followed, by advancing the instrument into the bladder about three cm., and sweeping it slowly through 180 degrees from side to side, step by step.
10. When the upper posterior quadrant has been in this manner completely studied, the instrument is rotated upward through 180 degrees from the patient's right to left, thus covering the most posterior field zone of the upper posterior quadrant. At the left point it is withdrawn the diameter of a field, and rotated to the right over 180 degrees. These three field zones commonly serve to cover completely every square centimetre of the upper posterior quadrant, otherwise called the apical or urachal quadrant.
11. By exactly the same procedure the lower anterior or retropubic quadrant is studied, one field zone at a time, each having a width of one cystoscopic field and extending from side to side through an arc of 180 degrees. As a rule, from two to four such zones complete the inspection of this and all other quadrants.
12. When the neck has been reached, as much as possible thereof is inspected in the same manner in a single field zone in both the ureterotrigonal and the retropubic quadrants.

If further study of the neck of the bladder is necessary, the retrovision telescope is substituted for the laterosion, and if this is not final in its findings, the urethroscopyscope is employed. No matter what instrument is in use, however, the same plan is followed, of passing through an arc of 180 degrees from right to left, and then withdrawing the instrument the width of its own field, rotating back again from left to right, and so on, until the entire neck has been thoroughly inspected. It takes longer to describe and read the details of this method than it does to follow it after a little practice. When this experience has been had, no one will ever think of giving up the plan. It will be noted that this method divides the bladder into anatomical divisions, viz., the fundus, floor or base, which are covered by the ureterotrigonal and subperiosteal quadrants and examined in accordance with paragraphs one to nine as just stated, and the apex and sides, which are included in the apical or urachal and retropubic quadrants, as laid down in paragraphs ten to twelve inclusive; which also embrace the neck of the bladder as perhaps properly an integral zone.

The following three case reports will serve to illustrate the facility with which these principles may be applied:

Case I.—Mr. B. O. Russian, white, aged fifty-five years, married, peddler, first seen December 6, 1912 (case 1260), referred by Dr. Benjamin T. Tilton and Dr. M. M. Apfel of Williamsburg. Diagnosis, enlarged prostate; two cal
culi in the bladder. History negative as to family, former personal, and former sexual facts; all venereal disease and sexual disorder denied. Present history began one year ago with frequency of urination: from ten to fifteen times by day, one or two times by night, with urgency fol-

Urgency is distinct, control incomplete, and shutting off of the stream is slow and interrupted. No catheterism. Pain is present in the testicle, rectum, and right loin, so that family physician suspected stone in that kidney. No change in sexual function. Physical examination shows

followed by comfort after evacuation. Blood noticed in the urine first on August 12, 1912, in rather large amount for a few hours. Urination has increased in frequency to every half hour by day and every four hours by night; almost doubling in the past few months. Stream has decreased in size and force, and is now forked and dribbling.

Urgency is distinct, control incomplete, and shutting off of the stream is slow and interrupted. No catheterism. Pain is present in the testicle, rectum, and right loin, so that family physician suspected stone in that kidney. No change in sexual function. Physical examination shows a man of very good health for his years. Soft, general, insensitive hypertrophy of the prostate. First urine fifty c. cm., clear; second urine without straining, fifty-five c. cm., clear; no residual urine. Calibre of urethra 24 F., admitting the Buëger cystoscope rather easily. Cystoscopy, December 6th, showed two stones in the bladder, behind a
moderately enlarged prostate. They were placed in the upper posterior quadrant, just beyond the equator of the bladder, about 20 degrees to the left of the middle line behind the left ureter. Uralysis of this patient's urine was done before operation, December 9th, and after operation, December 16th. Each was, age considered, normal; the phenolsulphonephthalein test showed high efficiency of the kidneys. Consequently, the operation of crushing the stones was undertaken and successfully carried out under ether at St. Mark's Hospital. Uneventful recovery followed.

The foregoing case report presents the application of these principles to foreign body in the bladder. The following notes show what they accomplish with respect to neoplasms and similar lesions of the bladder.

Case II. Mr. H. C. U.; United States, white, aged forty years, married, salesman (case No. 12754), April 21, 1913, referred by Dr. Browne Morgan, of Bloomfield, N. J. Diagnosis, multiple papilloma of the bladder. History negative as to family, former personal, former venereal, and habitual history. Present history began about four years ago with blood in the urine, more or less recurrent in type, from week to week and month to month, so that he had some blood for about one fourth of the time, always in small quantities and usually for part of the day only. Anything that disturbed the bladder increased the blood. Cystoscopy was performed on April 23d, and two papillomata were discovered, each requiring about three cystoscopic fields to cover. Their location would in the foregoing nomenclature be described as follows: The first tumor is located in the subperitoneal quadrant on or near the equator, just behind the left ureter, about 25 degrees to the left and extending almost to the left meridian. The second tumor is in the right meridian near the neck, so that it lies in part in the ureterotrigonal quadrant and in part in the retropubic quadrant, midway between the equator and the neck.

The foregoing record indicates how ready was the diagnosis and how accurate was the localization of the two papillomata from which symptoms seemingly trifling, though persistent, had for several years been proceeding. The case is an example of the importance of early cystoscopy in every case of blood in the urine.

Case III, F. H. L., German, white, aged forty-seven years, married, barkeeper (case 12769), May 15th, referred by Dr. R. W. Gelbach, of Hoboken, N. J. Diagnosis, papilloma of the bladder in the retropubic quadrant. Former general history negative; family history negative. Wife and two children well; no cancer, tuberculosis, nor syphilis. Past personal history negative. Former venereal history: Had urethritis once twenty years ago; treated by a physician for about a month by internal means; no complications or bladder trouble. Has always been in perfectly good health and without bladder symptoms until about three months ago, when he noticed for the first time a few drops of terminal bleeding. This returned a couple of weeks later, when he consulted Dr. Gelbach, who referred him to me. Uralysis showed slight turbidity; specific gravity 1.021, small excess of indican; decided trace of albumin; no sugar; normal urea; one tenth of one per cent. albumin, chiefly as constituent of pus; numerous pus cells; otherwise microscopically negative. Cystoscopy showed a bladder easily cleansed by irrigation, and painlessly distensible to 250 c. cm. In the retropubic

Fig. 2.—Shows the same plan of topography applied to the female bladder. Without necessity of a separate cut, the female urethra may be drawn in over the male in Fig. 1, and the same plan of procedure followed as with Fig. 1. There may be some physician who sees only female cases, to whom Fig. 2 will be of value.

This is another case showing the convenience of this method of recording cystoscopic findings, and also illustrating the importance of the earliest possible investigation of even small symptoms.

Each of these individuals is being benefited by fulguration. The second patient may do better than the first, inasmuch as the diagnosis was made so much earlier, while the growth is still small and perhaps not yet possessed of malign tendencies.

The value of this chart in the matter of urethroscopy is sufficiently set forth in the author's paper on Chronic Gonorrhoea in the Male, to which the reader is respectfully referred. It would be

---

1See New York Medical Journal, October 9, 1913.
superfluous to quote examples of urethroscopic records, or to quote others for cystoscopy than the three outlined above. There seems to be little doubt, however, that these details of case observation and record are worth the time they take.

45 West Ninth Street.

THE MODERN DIAGNOSIS AND TREATMENT OF GYNECOLOGICAL AND OBSTETRICAL PATIENTS WITH SYphilis.*

By J. Bentley Squier, M.D.,
New York, Professor of Genitourinary Surgery, New York Post-Graduate Medical School.

To essay in detail an exposition of the abstract matter of this paper, as outlined in the programme, would, I fear, owing to its comprehensiveness, jeopardize my position in relation to your society, toward which I entertain a profound sense of gratitude, and might perhaps, in view of the time necessitated in communicating the same, preclude the possibility of ever receiving a second invitation to address you.

Therefore, I shall more or less arbitrarily emphasize or minimize such topics which appeal to me as possessing points of greater or lesser practical importance, since, after all, this is the barometric gauge militating for or against a paper of this character. It is my purpose briefly to quote the findings of a number of the more recent publications, a list of whose authors will be given at the conclusion of the paper.

The value of the complement fixation reaction and its interpretation.—Here at once enters a number of factors, vital to the success of this exceedingly valuable test; but, with little fear of contradiction, I will venture the opinion that the consideration of greatest importance is the experience and dependability of the biologist conducting the test, whose report, in such cases as are clinically doubtful, should be supplemented by that of another equally experienced biologist.

Indeterminate reactions. Should the patient’s condition not indicate immediate intervention, a period of several weeks may be allowed to elapse without treatment, before taking another Wassermann test.

Determinate reactions in the absence of frambesia tropica and leprosy, according to Carl Bruck, one of the authors of this test, are (in the absence of faulty technic) positively pathognomonic of syphilis. Hence the importance of the requisite first mentioned, namely, checking up the reaction by a second biologist.

Countervailing influences. Little or no importance should be accorded a negative reaction in the presence of recent mercurial administration or a recent marked alcoholic indulgence.

Prophylactic salvarsan administration, so called, may be borne in mind, as it is a well known fact that in a number of cases where an indeterminate or negative reaction has been recorded, salvarsan ad-

ministration has been followed by an evanescent positive reaction. The field of usefulness of such a procedure would be largely limited to obtaining data as to a probable cure.

Doubtful cases. A few cases have come under the author’s observation in which a positive Wassermann reaction was reported by different biologists, yet the subsequent history of which, as well as later tests, tended to prove that the patients had never been luetic.

Finally, one should not lose sight of the value of clinical evidence, as well as the worth of diagnostic treatment, where such evidence conflicts with laboratory tests.

The luetin skin reaction. This may be regarded as the analogue of the von Pirquet test for tuberculosis. It consists in the application of a preparation of dead Spirochaeta pallidae to the scarified skin. According to its author, it is practically always positive in tertiary syphilis, while secondary cases rarely give the reaction. In other words, it is strongest where the Wassermann test is apt to prove weakest, and while certain syphiliographers would seem to diagnosticate tertiary lesions with it in preference to the Wassermann reaction, the consensus is, that this test has as yet failed to find a place of very much importance in the routine diagnosis of lues, the chief objection on the behalf of other authorities being, that while in administering the Wassermann test no complication may be anticipated, faulty technic in the preparation of luetin might constitute a veritable menace to the subject.

Differential diagnosis of skin disease in relation to the organs of generation. Many of us here are but too well aware of the almost insurmountable difficulties heretofore encountered in diagnostinating differentially, even in the face of laboratory aids then at hand, such lesions as lupus, carcinoma, recent ulcer, and syphilis of the vulva, and the none too easy solution of lesions of the nipples and breast, such as malignancies, gumma, syphilides, and psoriasis-like eruptions. In the light of the first chapter and the diagnostic aids therein mentioned, to err in these cases and times should indeed prove exceptional.

The hereditary stigmata of lues. It was the writer’s original intention to consider this topic somewhat at length, but later the conclusion forced itself upon him that to take up this inexhaustible subject briefly before a society of this character would appear inadvisable, inasmuch as to confine it to the confines of a few paragraphs in a paper where brevity constitutes so important an element would automatically prove fatally defective. The interested reader on this subject, however, cannot fail to be rewarded by a close study of Dr. Edmond Fournier’s observations, as translated by Dr. Leon Joseph Roth (1), as well as the compact but comprehensive work of Marshall (2).

Advances in the administration of salvarsan and neosalvarsan. In my own practice the use of neosalvarsan has almost entirely supplanted that of salvarsan for the following reasons:

First, simplicity of preparation.

Second, minimizing the number of preparation ingredients, and thereby reducing by that much the possibility of faulty technic.
Third, the possibility of the employment of a smaller volume of fluid for injection.

Fourth, diminished toxicity, with less reaction.

Mode of employment. The intravenous method is employed by me in practically all cases, inasmuch as no method of preparation of the drug has thus far been advanced which assures the patient a painless intramuscular injection of a sufficient amount of the drug; and the additional reason that there are many factors quite beyond our control affecting the rate of absorption of the remedy when thus administered.

Importance of freshly distilled water. The employment of water distilled on the day of administration cannot be overestimated. Inasmuch as it has been conclusively proved that, for the most part, excepting in florid cases, the violent reactions following the employment of neosalvarsan are due chiefly to the absorption of proteid products of dead bacteria contained in the water of dilution when any length of time has elapsed between distillation and use; whereas with faultless technic these reactions will rarely be encountered. Freshly distilled water should be used not only for the solutions, but also in the sterilization and cleansing of glassware, tubing, etc.

Time of administration. One should not, as heretofore, await the onset of secondary symptoms. This because it is of the utmost importance to society to render these patients innocuous at the earliest possible moment, and in the light of recent advances in laboratory technic (dark field illumination for spirochetes) one need not await the time necessary for the appearance of a positive Wassermann reaction. If we hope for an early cure of the patient, treatment must be instituted at the earliest manifestation of the disease.

Dosage. No fixed rule may be followed as to dose; each case being treated according to the particular indications. It is my custom in robust patients showing no contraindication to give the neosalvarsan equivalent of 0.6 gramme of salvarsan as soon as the diagnosis is confirmed; from three to five such doses being administered at weekly intervals. At the end of the series no delay is made in ascertaining the blood reaction, to determine the efficacy of the treatment, as that has already been amply demonstrated, and my chief concern is not one of scientific interest, but to cure the patient.

The much heralded cures by a dose or so of salvarsan which we were led to believe possible from the early reports of the drug and its actions, have failed to materialize with any sufficient degree of regularity to justify our discontinuing all treatments at this early period on account of the negative complement fixation reaction. It is my practice, therefore, to at once institute a vigorous and, with few intermissions, a persistent mercurial course. In women patients the doses will generally be smaller. An average maximum will be found to be the equivalent of 0.4 gramme of salvarsan.

As to hospital and office treatments. While many men of known conservatism regard this remedy as within the realm of office treatments, I have as yet been unable to bring myself to their viewpoint, and still conduct this procedure under the strictest aseptic precautions in a hospital, and advise rest in bed or in the reclining position for five or ten hours following the treatment. I will admit, however, that this may be due to a surgical training which has impressed me that even the operation of intravenous injection is one which carries with it some risk.

Contraindications—Neurotoxides, etc. The preliminary routine examination of eyes, heart, kidneys, and nervous system should, of course, be instituted, though it must be admitted that a decision as to where the indications end and the contraindications begin requires a pretty fine discriminating ability. Undoubtedly, I should not hesitate to employ the drug in a progressive luetic eye invasion, nor may a nephritis coexisting with a strongly positive Wassermann reaction in an otherwise robust patient be considered a deterring factor, as these complications have on numerous occasions been greatly improved after its use.

Blindness. A rare but none the less terrifying eventuality after salvarsan medication has by some been attributed to the toxicity of the drug, but this, it would appear, has been amply disproved by succeeding with additional injections of the drug in clearing up a number of these cases. At any rate, it must be by this time clear to all who have used it that neosalvarsan is by all odds the most innocuous form of arsenic.

Conditions necessitating caution in the administration of neosalvarsan. In chronic alcoholic cases, giving evidence of myocarditis, arteriosclerosis, and lesions of the cerebospinal system the administration of these drugs should be conducted with the utmost caution, and at first in minimum dose, with a view to ascertaining the patient’s degree of tolerance.

Mercurial medications. A broad conception of our present position as regards the subject of treatment of syphilis would appear to indicate: First—An early and intensive salvarsan or neosalvarsan medication, with a view, if possible, to curing the disease at once, or, failing in this, to remove the patient from the category of infective menaces at the earliest moment. Second—To supplement this with a vigorous and intensive mercurial treatment in earlier cases of from six months to a year, and in later cases of a somewhat longer period; the patient’s condition to be checked up clinically during this period, and following the treatment, by means of Wassermann and luetin reaction tests, if the latter be proved accurate, and finally, by means of a provocative salvarsan administration, as before outlined, to establish the fact of a cure.

The mercurials and iodides. Just a word concerning the older remedies and their administration.

First, month medication. While cases have undoubtedly occurred in the practice of many of my auditors of cured syphils, as proved clinically and by laboratory tests, it is none the less a fact that day by day new cases are being recorded of patients who have set up, probably, as the result of such treatment, a marked antagonism to all forms of medication. This statement applies with special force to yellow mercurous iodide, which drug is more entitled to place in the history of medication rather than in its present day practice. It too often produces an immunity in the spirochete to the germicidal action of the mercury.
Second, mixed treatment, so called, still constitutes a fair tideover; in other words, an interval treatment, or adapted perhaps to particular cases. It should not, however, be regarded as a routine measure.

Third, inunctions. The value of mercurial inunctions may not be gainsaid, and when it can be properly carried out as to purity of product, thorough disintegration of its globules, and the proper frictional application, this method still constitutes a most potent remedial agent in the treatment of this disease, and particularly so with children, as its administration carries with it no terrors.

Fourth, intramuscular mercurialization. Here we have two types of preparations to deal with, the soluble and the insoluble. Of the soluble preparations, there are many; most of which I have tried only to return to the bichloride. It suffices to state that two points may well be borne in mind in the preparation of a solution for hypodermatic use: First—Dissolve the mercuric chloride in the proportion of grain $\frac{3}{4}$ to two c. c. of an isotonic normal salt solution, as in this event a practically painless injection is assured. Second—To massage the parts gently but firmly for from five to ten minutes, thus reducing to a minimum the possible formation of indurated nodes. The advantages of soluble drugs are: First—relative painlessness; second—intensity. The disadvantage is too rapid elimination, necessitating too short intervals between treatments.

Insoluble injections. Included under this category may be briefly mentioned in the order of their intensity: Calomel in oily suspension; gray oil (hude grise of the French); salicylate of mercury in oily suspension, preferably in oil of sesame. Calomel in suspension constitutes undoubtedly the most powerfully intensive of all the mercurials. It should not be used as a routine measure, as it is quite painful and not unattended with danger. Rather reserve it for the urgent type. Of the others, salicylate of mercury suspended in oil of sesame will be found a most effective routine measure. In a ten per cent. suspension, one c. m. will be the equivalent of $\frac{3}{4}$ grains. The advantages in the employment of this type will be found in the fact that treatments are, as a rule, needed only at intervals of once in four to seven days as the case may be; that a more or less constant absorption is going on during this time; and that it is perhaps the least painful of the insoluble preparations.

CONCLUSION.

To summarize the foregoing, one might connote the following, as points of importance:

First. Treatment should be begun at the moment diagnosis is certain.

Second. To assure success it must be as intensive, both from an arsenical and mercurial standpoint, as the history of the case and the patient's physical condition warrant.

Third. The time heretofore wasted in discontinuing treatment and the Wassermann test during the early months of the disease may be very well employed, and to the patient's benefit, in endeavoring to eradicate the disease.

Finally, and this point cannot be too strongly emphasized, that in the treatment of this disease, not only from the standpoint of the physician's own integrity and his bounden duty to society, but also of the welfare of his patient, he should under no circumstances attempt to treat a disease of such widespread effect and sinister influence without having given much study to the present conception of the management of the disease.

In my own city a widespread hospital movement is on foot in an endeavor to have all luetic patients referred to a special department for the treatment of syphilis. Such a department is not to be attached to some other special department, but to have a distinct entity. It is to be in charge of men who have given special study to the disease as a whole—not merely of some special phase, such as skin syphilis, eye syphilis, or genitourinary disease, etc. Only in this way can patients be given the scientific care which modern medicine demands, and a successful concerted attack be made to rid our social life of this greatest of scourges. The century just opened has already given us a knowledge of the cause of syphilis, a blood test of intense diagnostic value and a therapeutic agent of almost supreme effect. It remains with us all to so utilize this triumvirate, that long before the history of our present century is written, the death knell of those succumbing to the ravages of syphilis shall cease to toll.

SURGICAL INDICATIONS OF CERTAIN GASTROINTESTINAL SYMPTOMS.*

By John Douglas, M. D.,

New York,

Clinical Professor of Surgery, University and Bellevue Medical College; Visiting Surgeon, Bellevue Hospital; Senior Assistant in Surgery, Luke's Hospital.

The busy general practitioner always has a considerable number of patients with gastrointestinal symptoms under his care. Frequently the symptoms are not apparently very serious and are easily amenable to treatment; but there will always be a certain number of patients, however carefully and judiciously treated by medical means, who remain uncured and present great difficulties of diagnosis. For if a correct diagnosis be made, the indications for treatment are apparent.

Usually no one symptom is a positive index of the condition present. Vomiting may be present in almost any abnormal gastrointestinal condition. Epigastric pain is a symptom of acute gastritis, ulcer, carcinoma, adhesions, gallstones, cholecystitis, pancreatitis, gastroptosis, etc. Hematemesis, or coffee ground vomitus, occurs in ulcer, carcinoma, anemia, cirrhosis of the liver. Melena is a symptom in ulcer of the duodenum, but tarry stools or occult blood may be found in the feces from other causes, occult blood being even demonstrable by the

*Read by invitation before the Orange Medical Society, June 24, 1912.
finer laboratory tests after the rough use of a toothbrush. Diminished acidity, or absence of free hydrochloric acid, while usually occurring with carcinoma, may be present in an atrophic stomach, chronic pancreatitis, or pernicious anemia, and certainly frequently occurs when no carcinoma is present; while we know that carcinoma frequently, if not usually, develops in an old ulcer, and here free hydrochloric acid is often present and the total acidity may not be decreased. General abdominal pain may be due to a simple enteritis or colitis, or it may be the first symptom of a beginning appendicular inflammation. volvulus, mesenteric thrombosis, or intestinal obstruction. Obstinate constipation, while most frequently functional in its etiology, may be caused by some mechanical condition or be a symptom of unrecognized carcinoma of the large intestine.

The functional derangements of the stomach and intestines, acute and chronic gastritis, enteritis, and colitis, are wholly within the province of the internist. Carcinoma of the gastrointestinal tract, perforation of a gastric or duodenal ulcer, acute gangrenous appendicitis, general peritonitis, intestinal obstruction from any cause, can only be treated by surgical procedure, and then only treated successfully after early diagnosis. Therefore, the success of the surgeon depends mainly on the general practitioner who first sees the case. Between these two classes of cases, those obviously medical and those obviously surgical, are those cases of ptosis of the stomach and transverse colon, dilatation of the stomach due to pyloric obstruction caused by an old healed ulcer or adhesions from a cholecystitis, and chronic appendicitis without distinct severe attacks, but attended with irregular pains and tenderness in the right inguinal region and a variety of gastric symptoms. It is the means of early diagnosis in those cases obviously requiring surgical treatment, and the recognition of the indications for surgical intervention in the latter class of cases when medical means have failed to effect a cure, that will be dealt with in this paper.

First, to consider carcinoma of the stomach. In the beginning, gastric carcinoma is a local condition curable by operation, not presenting great technical difficulties when the lesion is situated in its most common location, the pyloric third of the stomach. With earlier diagnosis and improved technic, the immediate mortality has been reduced from sixty-four per cent. in Billroth's original series of cases, to four per cent. in the last fifty cases reported from the Mayo (1) clinic at Rochester. The same article reports thirty-six per cent. alive after three years and twenty-two per cent. after five years. These results are more favorable than those usually reported. Weil (2) reports on 104 patients who survived the operation of resection for carcinoma of the stomach in Kuttner's clinic during the past five and one half years. Of these, forty patients are still alive; eight for more than three years. Many cases, however, are referred for operation only after extension of the growth, glandular involvement, and metastases have made radical removal with any prospect of permanent cure impossible. Therefore the results of operation are much worse than they would be if the resection could be done while the carcinoma remained a local condition. In a disease the non-operative mortality of which is 100 per cent. within a short time, surely every effort should be made for early diagnosis.

The textbooks give cachexia as a symptom of carcinoma of the stomach, but if the diagnosis is not made until cachexia appears it is usually too late then to operate with any prospect of a cure, although even then the symptoms may be greatly ameliorated, with great improvement in the general condition of the patient and prolongation of life. If the patient presents gastric symptoms, and examination shows the presence of a mass in the pyloric region, or a retention of food in the stomach for eight or ten hours after eating, indicating an obstruction at the pylorus, the probabilities are so strongly in favor of carcinoma that an operation is indicated, for even though a benign obstruction caused these symptoms, the symptoms could only be relieved by operation. If, furthermore, coffee ground vomiting is present, this also favors the diagnosis of carcinoma. In addition, the laboratory tests should be made to confirm the diagnosis, but always remembering the element of uncertainty in each test. When a tumor and signs of obstruction and coffee ground vomiting are present, the laboratory tests are of less importance than in cases where these signs do not exist, as would be the case in carcinoma upon the lesser curvature, which would not cause obstruction and would not be palpable.

Examination of a test meal showing diminished acidity, absence of free hydrochloric acid, presence of lactic acid and Boas-Oppler bacilli, is the rule in carcinoma of the stomach, but it must be remembered that in the absence of obstruction and dilatation, lactic acid and Boas-Oppler bacilli may be absent, that the total acidity and hydrochloric acid may not be diminished, or may even be increased, when the carcinoma is developing in an old chronic ulcer, or the pyloric end of the stomach is not involved; and also that diminished acidity and absent free hydrochloric acid exist without the presence of cancer. Radiographs of the stomach after a bismuth meal consisting of two ounces of bismuth carbonate in some form of fermented non-aerated milk, are also valuable confirmatory tests, but here also careful study and interpretation of the plates are necessary, as adhesions about the pylorus and peristaltic waves may lead to a false interpretation. Figure 1 illustrates a typical radiograph of a carcinoma of the pyloric third of the stomach; Figure 2, radiograph of stomach remaining three weeks after partial gastrectomy; Figure 3, photograph of portion of stomach removed (Figs. 1, 2, and 3). This patient was operated on in April, 1912, and one year after operation had gained twenty-six pounds and had no gastric symptoms.

The glycyrhptophan test depends on the fact that the stomach secretions do not split up the proteids further than to peptones, any further chemical process requiring an additional ferment not normally found in the stomach, although such a ferment is present in cancer cells. Here, also, a great element of uncertainty is present because blood in
the stomach, or regurgitation of some of the duodenal contents into the stomach, would make the test positive; and, furthermore, the test depends on a delicate color reaction, which in doubtful cases makes the final decision uncertain as to whether the color change is sufficient or not to be positive or otherwise. Recently, further doubt has been thrown on the value of this test by the demonstration that saliva, especially from an infected oral cavity, perhaps due to the bacteria contained therein, is capable of splitting glycyltryptophan. The agglutination tests and cobra venom tests, on which some work has been done, have not been sufficiently developed as yet to be of any clinical value. Fuginami (3) has suggested an aid to diagnosis by means of the radiographic study of the relative position of two capsules of bismuth, one sinking and one floating in the fasting stomach, to test the amount of secretion and stagnation in the stomach. When these various chemical and radiographic tests can be made, they are an aid to confirm diagnosis, but the physical signs of an epigastric tumor, or of obstruction with or without a palpable tumor, in the presence of anorexia and other gastric symptoms are, without these tests, a sufficient indication for operation. These tests mentioned are of especial value where the carcinoma is on the lesser curvature and does not cause obstruction or forms a palpable tumor.

The treatment of acute ulcer of the stomach or duodenum is medical. Even in the presence of tenderness, superacidity, and melena, notwithstanding medical treatment, indicate the presence of an ulcer requiring surgical treatment. This is true not only because the symptoms do not respond to proper diet and medication, but because of the danger of perforation and the prospect of the chronic gastric ulcer undergoing carcinomatous changes, a fact which is becoming more generally recognized. Furthermore, the statistics show that a comparatively small number of cases of chronic ulcer are cured by medical treatment. Bulstrode, in an analysis of five hundred cases in the London Hospital, concludes that gastric ulcer recurs or relapses in at least two fifths of the cases which are apparently cured. Patterson (4) succeeded in tracing seventy-two patients out of a series of 147 that
were discharged from the hospital as cured. Of this series, forty still had signs of gastric ulcer, five had been operated on, one died of carcinoma, twelve had no signs of gastric ulcer, five were apparently not cured, and two others were apparently cured; so that sixty-four per cent. of the cases were uncured by medical means. Mayo Robson reports ninety per cent. of a series of three hundred cases completely relieved of all symptoms by operation, with an immediate mortality, excluding perforation, of three per cent. Moynihan has reported 192 consecutive operations for duodenal ulcer without a death.

It is not alleged that every case of gastric or duodenal ulcer is permanently cured by operation, as it is known that in a considerable proportion of patients on whom gastroenterostomy has been performed, while the symptoms are improved or disappear, and the ulcer is probably healed, later on there may be a return of the symptoms due to the recurrence of the old ulcer or the formation of a new one. This has been explained by the gradual contraction of the gastroenterostomy opening, the pylorus remaining patent, and a return of the etiological factors which produced the original ulcer. Perhaps with excision of the ulcer when feasible, and occlusion of the pylorus in addition to gastroenterostomy, our statistics of permanent cure will improve. But even at the present time the percentage of cures of chronic ulcer is better under surgical than medical treatment, and the danger of perforation or carcinomatous degeneration far less. (See Figures 4 and 5.)

Perforation of a gastric or duodenal ulcer is recognized by a previous history of gastric disturbance, although often quite indefinite, and the incidence of acute severe epigastric pain, shock, retching, occasional vomiting, elevation of temperature and pulse rate, and an increase in the total and polymorphonuclear leucocyte count. In addition to the symptoms of shock, examination shows marked local tenderness and rigidity in the epigastric region. If the perforation is small and has been gradual, and had been preceded by a local peritonitis and the formation of adhesions, the symptoms may remain localized and the symptoms of a local peritoneal abscess develop; but more commonly the symptoms of a general peritonitis rapidly appear, from escape of the contents of the stomach or duodenum into the abdominal cavity. It is especially to be remembered that the leakage from the perforation is apt to run down along the right side of the abdominal cavity, and the symptoms therefore simulate those of acute appendicitis. The mortality of operations for perforation of a gastric or duodenal ulcer increases with each hour that operation is deferred after perforation occurs; hence, the importance of an early recognition of the symptoms.

As a result of chronic ulcer, adhesions may be formed and cause constriction at the pylorus, with resulting obstruction to the passage of food into the duodenum; then stagnation with its symptoms is present. The same symptoms of pyloric obstruction may sometimes result from a cholecystitis or cholangitis, which causes a chronic inflammation in the region of the pylorus and duodenum; and while these symptoms are often vague and indefinite, consisting of pain, dyspepsia, vomiting, and tenderness in the epigastrium and right hypochondrium, they do not improve permanently under medical treatment. If the X ray after a bismuth meal shows definite signs of this obstruction being of a mechanical nature, then surgical procedure only can effect a cure. A word might also be said here in regard to surgical intervention in congenital stenosis of the pylorus. While pyloric spasm in infants occurs, there is a true hypertrophic stenosis of the pylorus from which it must be differentiated, and which calls for operation to effect a cure. The symptoms are persistent obstetric vomiting, a palpable small tumor at the pylorus, visible gastric peristalsis, epigastric fullness and lower abdominal retraction, the constipated meconiumlike stool, and the absence of curds in the stool. As a test of the patency of the pylorus, carmine or charcoal may be administered and looked for in the stool, and the bismuth radiograph may be employed. Scudder (5) quotes Monier's statement that the mortality of the expectant nonsurgical treatment of these true hypertrophic stenosis cases is from eighty to ninety per cent., while the surgical mortality, which from 1868, when operative treatment was first essayed, to 1905, was 40.5 per cent., between 1905 and 1911 was reduced, in thirty-three cases of his own and from the literature, to nine per cent.

Ptosis of the stomach is a condition which, while frequently unrecognized, is usually amenable to mechanical treatment, but sometimes calls for surgical intervention. Gastroptosis may occur alone or as a part of a general visceroptosis (Glehnard's disease). With the advent of the bismuth radio-
graph taken in a standing position, our conception of the position of the normal stomach has been greatly changed, the stomach being found normally suspended in a vertical rather than a horizontal position, but in some cases the stomach is so far down that the pyloric end of the greater curvature extends well down to the level of the pelvis, and the lesser curvature is below the level of the umbilicus. The stomach assumes a fish hook shape, and the musculature is insufficient to raise the food to the level of and expel it through the pylorus. Stagnation ensues, as in the water trap of the plunger, and this type of stomach has been called by Satterlee (6) the "water trap" stomach. Drug treatment for this condition is usually ineffectual, but much may be done by lavage, regulated exercises, postural treatment, abdominal belts or corsets, and forced feeding to increase the muscular power and correct the relaxed condition of the stomach wall. But when vomiting or pain persists, and there is no improvement under medical treatment, surgery may effect a cure, as is shown by the brief history and radiographs before and after operation of the following patient:

L. E., aged thirty-one years, housewife, referred by Dr. G. R. Satterlee. Has always been troubled by indigestion, gas in the stomach, but did not vomit or have severe pain until the present attacks began about one year ago. For the past year has had severe attacks of vomiting, lasting sometimes twelve hours, the vomiting being accompanied by copious eructations of gas. Attacks occur without any known exciting cause. Appetite fair, but has eaten little on account of vomiting. Has lost a great deal of weight. Says she weighed 160 pounds; now weighs less than 100 pounds. Bowels very constipated. Insomnia and general neurasthenic symptoms. Bismuth radiograph (Fig. 6) shows marked ptosis of stomach of water trap type. After careful medical, postural, and mechanical treatment had failed to effect any improvement in the case, a gastroplasty was done in July, 1911. That the relief has been permanent is shown by the radiograph (Fig. 7) taken in October, 1911, and by the improved general condition of the patient at the present time. She now has no stomach symptoms, almost two years after operation, and weighs 120 pounds.

Three other patients, operated upon subsequently for a similar condition, show equally good results. In these cases a gastropexy gives better end results than a gastroenterostomy; but no operation should be attempted unless medical treatment has failed to effect a cure.

Of course, in carcinoma the only treatment is...
this country and abroad. Most of them say not, as it increases the risk; others say that if the rupture had only existed for a short time, and there is little peritonitis, they advise a posterior gastroenterostomy in those cases where the rupture is near the pylorus, and that closure of the perforation will increase or cause stenosis.

The limits of this paper prevent any reference to the acute diseases of the intestine requiring surgical treatment, and only allow of brief reference to some of the chronic conditions which fail to respond to medical treatment. Acute appendicitis is usually not difficult of diagnosis, and the indications for immediate operation are well recognized.

Also, if a patient has two or more subacute or mild attacks he is usually advised to have the appendix removed. There is, however, a class of cases in which there is a chronic low grade inflammation in the appendix with dragging pains in the right inguinal region, more severe at times, especially when there is some general abdominal distention with gas, moderate tenderness on pressure over the appendix, and various dyspeptic symptoms, accompanied as a rule by gastric supersecretion. The diagnosis is aided by distending the colon with air by means of a rectal tube and bulb. When the colon is so distended, the pain and tenderness over the appendix, if it is diseased or bound down by adhesions, is increased. Beside relieving the symptoms, an additional reason for the removal of such chronically diseased appendices is, that they are now suggested as a possible etiological factor in the development of cholelithiasis, and gastric or duodenal ulcer.

There are, however, a number of patients who have suffered from pain in the right inguinal region that have not been relieved by an appendectomy alone. Our knowledge of these cases as a result of operative experience, post mortem examination, and the study of radiographs, has shown other conditions in the right inguinal region besides the inflammatory lesions of the appendix, and a recognition of these conditions, with the proper diagnosis and suitable operation, will prevent the disappointment resulting from a failure to cure the patient after the removal of a normal appendix. The symptoms complained of are pain and tenderness in the right inguinal region, sometimes developing into severe attacks, at times accompanied by vomiting, but without as a rule much or any temperature elevation, after indiscretions of diet or when the patient's constipation has not been relieved. Examination shows distention, gurgling, splashing, and tympany in the distended cecum, and a bismuth radiograph demonstrates that the cecum is distended and sometimes pouted to such a degree that it occupies a position low down in the pelvis. Frequently the mesoappendix is unusually long. This condition has been described in the German literature under the term "cecum mobile" (Wilms) (8), but in some cases the dilated atonic condition would appear to be of more importance than the mobility.

![Fig. 6.—Typical radiograph of case of gastroptosis of the water trap type.](image)

![Fig. 7.—Radiograph of stomach shown in Fig. 6, three months after gastropexy. Patient almost well two years after operation.](image)
It is frequently associated with a general enteritis, and while, perhaps, partly due to a developmental fault, is added to by a general atomic condition and improper diet and care of the bowels. When medical treatment directed to the correction of these conditions fails, it would appear that surgery could give relief, as a number of successful cases have been reported, either by fixation of the ptosed or by plication of the distended cecum. These operations, however, have yet to stand the test of time before their final efficiency and permanent worth are determined.

In other cases, where pain and gaseous distention occur in the right inguinal region, we may find about the cecum and ascending colon, or at the hepatic flexure, membranous adhesions, the so-called Jackson's membrane (10), attached to the parietal peritoneum, constricting the involved intestine, and preventing peristalsis (membranous pericolicis). This condition is believed by some writers to be due to a chronic inflammatory condition in the appendix, or to a chronic colitis with intestinal putrefaction and a low grade inflammation in the serous coats with connective tissue formation. Other writers believe it to be a congenital condition, due to a developmental fault, and caused by improper or incomplete rotation, migration, and adhesion of the colon in the fetus. Recent literature (Gerster (11), Pilcher (12), Jackson (13), Connell (14), and others) is full of citations of cases and illustrations showing not only these bands between the parietal peritoneum and the intestine, but between the different portions of the large intestine, the ascending colon and first portion of the transverse colon being sometimes found bound together so as to suggest the two barrels of a double barrelled shotgun. Separation of these adhesions and division of the bands where present, remove the mechanical prevents to peristalsis, while removal of the appendix without any interference with these membranous adhesions, is apt to be followed in some cases by recurring pains in the right inguinal region. It is important, however, that every effort be made to prevent the reformation of these adhesions, by carefully covering the denuded surfaces by peritoneum where possible, the use of sterile petrolatum on raw surfaces, postoperative catharsis, and postural treatment. The presence of a Lane (15) kink should also be looked for and corrected if present.

The recognition of these various pathological conditions in the right inguinal region is so recent, that the etiology of each one is not yet exactly known, and while a considerable number of patients have been reported as cured, the proper operative procedure and indications to meet each condition cannot be definitely settled until sufficient time has elapsed to demonstrate the end results. It is recognized that the symptoms of a majority of such patients can be relieved by nonoperative means, and should be so treated, but it is believed that there are always a few patients that the most careful dietetic, mechanical, and medical means will fail to cure, and in these the proper operative procedure will give good results.

Finally, it seems worth while to consider briefly a condition which, while apparently unusual, in the light of our present knowledge, does not seem to be as rare as previously supposed. Diverticulitis of the sigmoid was occasionally described as a curious post mortem finding, and as recently as 1904, in Nothnagel's Encyclopaedia, is written: "these lesions are chiefly of anatomical interest and have very little clinical significance." (Figure 8.) In 1907, Mayo reported five cases, and was able to collect only eighteen cases from the literature. Since then a large number of cases has been reported. The symptoms depending on the pathological condition present resemble those of appendicitis on the left side. Thus there may be mild attacks of inflammation about the diverticula, a chronic inflammation with acute exacerbations, resulting in a local peritonitis with or without thickening of the walls of the intestine, or perforation with the formation of a local abscess, or general peritonitis. The local abscess may rupture externally, into the bladder, or into the rectum, and thus a fecal fistula or vesicointestinal fistula may develop. And it has furthermore been shown that the diverticulitis predisposes to the development of carcinoma. It is probable that many of these cases have been previously mistaken for carcinoma with perforation, when a diagnosis has been made at all. When the need of op-

The importance of serological analyses in neurology.

By D. M. Kaplan, M. D.

New York, Director of Laboratory, Neurological Institute.

(Concluded from page 312.)

Platt, in his book on the significance of the Wassermann reaction in psychiatry, placed considerable value on the absence of this reaction in the spinal fluid and its presence in the serum, considering this combination as significant of cerebrospinal syphilis. He has since then (1900) changed his attitude regarding this point. Among 114 cases observed by me, sixty-seven patients showed this form of serological condition. Six patients from this group were considered general paralytics, and the three patients spoken of before who improved after treatment were from this group. As the pathological basis of general paralyas is originally of a luetic nature, and as there are a few cases of cerebrospinal syphilis with a comparatively low cell count which is not the result of treatment, one may not be entirely wrong in considering those cases with from fifty to eighty cells per c.mm. as transitional stages from cerebrospinal lues to general paralyses. This is especially emphasized where the Wassermann reaction is negative in the spinal fluid, thereby conforming to the French conception of the serological state of early or incipient paralyses. In Nonne's before mentioned article, on pages 214 and 215, an attempt is made to differentiate serologically general paralyses from cerebrospinal syphilis. From a careful analysis of his table it is hardly possible to obtain any differentiating features which would enable the physician, who may be in doubt, to decide either one way or another. Although I fully recognize the existence of borderline cases, I nevertheless consider the serological picture of the full fledged general paralytic in its typical form as decidedly different from the typical picture of cerebrospinal lues, provided that in the latter therapy has not been efficient and recent. My differentiation is as shown in the following table.

The findings according to Nonne are as follows:

- General paralyas or taboparalyas. Serum Wassermann plus in nearly 100 per cent. Pressure increased. Phase I positive (in ca. ninety-five to 100 per cent).
- Cerebrospinal lues. Positive in nearly eighty to ninety-five per cent. Frequently increased. Only exceptionally negative. Like phase I, positive.

This exposition of the serological differences does not take into consideration the possible effects treatment may have on a positive serology in cerebrospinal syphilis, a condition which is known to be markedly influenced by specific therapy. In my experience the chief guide in the serological differentiation between the two diseases is the cell count. It was stated before that tabes may give at times the serological picture of cerebrospinal syphilis, but no matter how recent the development of a general paralya, it will never show the serological picture that is found in untreated typical cerebrospinal syphilis. Another characteristic feature of general paralyas is to be found in the intensity of the Wassermann test; this item is marked in the offered table as strongly positive. It is not infrequently possible to foretell in the early stages of hemolytic incubation (last stage of the Wassermann reaction) which serum will remain positive to the end. Theoretically it may be argued that the greater the quantity of reagin units, the stronger the inhibitory power of the antigen reagin combination, and the earlier the manifestation of complete inhibition. In the sera from the majority of patients with general paralya this peculiarity showed itself earlier than in any other paralytic nervous disease. My laboratory associates frequently remark that this or that serum behaves like a general paralya serum; in the majority, these comments prove to be correct. At this juncture it is of interest to note that the few cases of so called tabes which subsequently turned out to be general paralya also showed this early sign of intensity in inhibition. The same is true of the patients with cerebrospinal lues whose capacity for general paralya was established serologically (cell count globulin) as well as clinically.

The importance of general knowledge of the use of specific drugs before a serological verdict is rendered can be seen from a study of the tables on posttherapeutic negativation. It will be shown there, that what may have been a distinct serological type before treatment, becomes so changed after proper therapy, that it no longer presents the typifying characteristics which it showed before, in fact the picture may become absolutely normal.

L = lymphocytes. P = Polymolecular cells. W+ = Weakly positive.
The hyperlymphocytic type of tabes lends itself most advantageously to the production of a negative serological result after treatment. Very often clinical improvement goes hand in hand with the serological, unless the patient is a candidate for taboparesis. The serological change in most instances resembled that given under Case 1. The serological changes in Cases 11 and 111 were very insignificant; unquestionable symptoms of taboparesis developed later in these patients. It will be recalled that a case diagnosed as tabes whose serological condition offers great resistance to the production of the negative picture by treatment, should be looked upon as a beginning general paresis. Besides these two instances there were several other patients not included in the hyperlymphocytic group who retained their initial serological status, regardless of treatment, and who subsequently became affected with general paresis. Case IV illustrates the posttherapeutic serologically negative tabes. The same can be said to a certain extent of Cases V and VI. It is a fact that treatment of hyperlymphocytic tabes is very gratifying both to physician and patient. The specific treatment, as in Case VII and in other similar serological instances, resulted in a most rapid decline in the health of two patients, one dying after three, the other after eight weeks. Tabes with a negative serological reaction is best left alone, the primary pathological condition probably being a degenerative process instead of an exudative one. Obersteiner has shown that tabes may arise upon an inflammatory basis. In this type of cases there is an original meningitis of varying intensity which causes a constriction of the fibres of the posterior roots as they enter the cord and an ascending degeneration of the posterior columns. It is safe to accept a cell count of over sixty as significant of such a condition.

It is safe to accept a cell count of over sixty as significant of such a condition.
condition was most likely cerebrospinal syphilis and not general paresis. It is not to be denied that general paresis often shows remissions and inter-
missions in its clinical course, but the cases are rare indeed where such improvement is as lasting as in the case cited. It is my conviction that the sporadic cures obtained in certain cases of general paresis to be found in the literature of the pre-
serological days of neurology, were cases like the one described above, cerebrospinal lues clinically re-
sembling general paresis.

Case iii portrays the Pfau type of cerebrospinal lues, with a negative Wassermann reaction in the fluid and a positive one in the serum. This patient was restored to good health, which, after a lapse of two years, he still enjoyed. His serological status became entirely normal, a condition to be obtained but rarely in cerebrospinal syphilis; for the cells, at least, seldom become entirely normal in number. Had this patient presented himself at another institu-
tion and given no information as to his previous treatment it would have been rather difficult to cor-
raborate serologically the clinicians' diagnosis of cerebrospinal lues. The fourth patient came to the author to obtain relief from his gastric disturbances. He was treated for two years for gastric catarrh without obtaining any relief. The absence of any abnormalities in his gastric chemistry, to-
gether with the presence of exaggerated knee jerks and unequal pupils that reacted sluggishly, suggested to me that the pains were girdle sensa-
tions, and a provisional diagnosis of cerebrospinal syphilis was made. The serological study proved that the contention was correct. After treatment with salvarsan his active symptoms disappeared and he was able to attend to his affairs. The fifth patient, regardless of the gradual reduction to negative, did not improve clinically. In Case vii a marked improvement resulted from the treat-
ment and the patient still enjoys good health after eighteen months. As can be observed in the chart, the production of a negative serological re-
action was complete a few weeks after the fifth dose of salvarsan. During the process of salvarsaniza-
tion the patient was asked to report for serological observations, and at one time he showed a be-
ginning return of the pleocytosis. Evidently the process of a putrid nervous affection cannot be cur-
tailed in every instance by a few doses of salvarsan, for as soon as conditions favorable for a return of the exudative process present themselves the serological aspect will tend to assume its previous intensity. Thus it is possible to detect early the return of the pathological process, the serological study again furnishing the index for further therapeu-
tic activity, as was the case in the last patient scheduled.

The treatment of general paresis with the various antiluetic remedies, I believe, is considered by those who have had extensive experience with this disease as being of no avail. It seems to me that where lasting benefit was obtained in a case diagnosti-
cated as general paresis it is safer to set aside for the time being this diagnosis and consider it a cere-
brospinal syphilis. The results, as far I have been able to ascertain, are by no means encouraging. The first patient died without any premonitory mani-
festations twenty-four hours after the last injection of salvarsan. In Case ii the same result followed two days after the last injection, the patient dying in stupor following a convulsion. Case iii showed not the slightest improvement and is at present in a stage of paretic decline. The same is true of Case iv. The fifth patient died thirty-six hours after the last salvarsan injection. Another patient whose serologi-
ical status is not presented has had seventeen full doses of salvarsan intravenously. On one occasion his cells in the spinal fluid were normal in number, regardless of the fact that the Wassermann reac-
tion was positive in the fluid. Two months later, having recovered from a convulsion and a stupor that lasted thirty-six hours, his serological exami-
nation again showed thirteen cells, together with the other positive constituents. These experiences do not argue against the use of salvarsan in para-
hes of the nervous system in general, but rather discourage its use in a disease like general paresis, which when fully developed offers very little hope of checking its progress. These tables of post-
therapeutic changes are designed for the clinician, to serve as a gauge for his therapeutic efforts, and also to enable him to foretell the advent of a gen-
eral paresis in a patient with symptoms of tubes, and to increase his efforts in the treatment of a case with cerebrospinal lues. It also shows that a nega-
tive serological reaction is by no means a rarity even in general paresis, and should surprise neither the clinician nor the laboratory worker. In Case iii we see the exception to the rule in the behavior of the cell count, as compared with the Wassermann test. We see in this instance that the latter re-
mained positive, regardles s of the absence of a pleo-
cytosis. Although this is the only occurrence in general paresis which came under my observation, it nevertheless shows that hard and fast rules do not exist in serology. Regardless of the rendering negative of the serological reaction in this patient, clinical improvement did not take place. I am inclined to consider the appearance of negative serological findings in general paresis as a sign of the approach of unpleasant symptoms. It is to be recalled that Parkinson noted a fall in the cell count during the decline and a rise during lucid intervals. My experience partly corroborates the these observations; in the majority of instances those who showed the smallest number of cells or a negative serological character were patients who were bed ridden, with bed sores, or were moribund.

The Negative Types.

Six patients with amyotrophic lateral sclerosis showed no deviation from the serology of healthy individuals, sixteen patients with multiple sclerosis gave three positive Wassermann reactions in the serum, five progressive muscular atrophy were normal, ten paralysis agitans, six syringomyelia, two myasthenia gravis, twelve cerebral arteriosclerosis, five polyneuritis, eight sciatica, one osteoarthritis lumbalis, three erythromelalgia, seven neurasthenia, one hydrophobia, two amaurotic family idiocy, thirty epilepsy, three gave positive Wassermann reaction in the serum, eight thrombotic hemiplegia, two positive in the serum, fifteen hemorrhagic hemiplegia, one positive in the serum, twenty-three compression of the spinal cord, one positive in the spinal fluid, fourteen brain tumor, four chronic hydrocephalus, nine anterior poliomyelitis. Of the psychoses the following were observed: Five toxic, four traumatic, two functional, twelve alcoholic, (one positive in serum), fifteen dementia praecox (two positive in serum), five senile dementia, four manic depressive insanity, two paranoia, two anxiety depression.

The lesson to be learned from a study of the negative serological types is that they should not be confounded with the types showing some of the characteristics of a neurological syphilis. The patients with multiple sclerosis had a positive Wassermann reaction in the serum admitted a syphilitic infection. In two instances this was contracted after the characteristic symptoms of multiple sclerosis had manifested themselves. Of the two positive cases of thrombotic hemiplegia one patient admitted an infection and both improved markedly after salvarsan. Of the thirty epileptics one admitted an infection and showed in his fluid thirty-two lymphocytes; two denied an infection, and the history of the fourth was very suggestive of syphilis. One case of dementia praecox gave a specific history, the other showed no evidence of a lues in the history nor in his physical status. In view of the uniformly negative results in this nonsyphilitic material, I believe I am justified in asserting that at least as far as neurological serology is concerned, it is safer to gauge one's biological reagents so that they will eliminate any chances of stamping an individual with syphilis who has not come in contact with this disease. The harm done by reporting negative on a syphilitic patient is very slight, and his chances of escaping specific treatment are small indeed.

Spinal Cord Compression.

The characteristics of the spinal fluid in compression of the spinal cord consist in an excess of protein matter and an absence of pleocytosis. In eight instances the fluids were yellow. Six of these proved to be endotheliomata, and the color of the other two originated from cysts formed in tumors. Upon exposure of the cord in a few instances no tumor could be demonstrated, but instead very fine connective tissue trabeculae compressing the cord.

Conclusions.

1. The Wassermann reaction is not present in the spinal fluid in all cases of syphilitic and parasyphilitic disease of the central nervous system.
2. The use of increasing amounts of spinal fluid for the Wassermann test ("Auswertungs Methode" of Hauptmann) is a procedure capable of giving rise to nonspecific inhibition in patients who did not come in contact with this disease.
3. Serologically all nervous diseases are divided into two general and easily distinguishable classes, the negative and positive types. The negative type represents the nonnecrotic nervous diseases, the positive type the syphilitic and the parasyphilitic diseases.
4. In the positive type group further differentiation is possible by serological investigation in cases where physical differentiation is difficult, such as between general paresis and cerebrospinal lues.
5. Active and proper treatment markedly alters serological pictures in many of the positive types. Such alteration may go on to any extent, even to the reduction to a complete negative picture. The greatest change to the negative occurs in cerebrospinal lues and the least in general paresis.
6. In the cell count in tabes may be found an index for or against treatment.
7. Fully developed general paresis is best left untreated.
8. Spinal cord compression from tumors or other causes shows a protein excess and an absence of pleocytosis.

THE RESPIRATOR: AN APPLIANCE FOR RESUSCITATION BY PRODUCING ENFORCED ARTIFICIAL RESPIRATION; REPORT OF 163 EXPERIMENTS.

By H. E. Tompkins, M. D., D. D. S.,
New York.

The purpose of the respirator is to produce resuscitation by means of enforced artificial respiration, in the simplest manner possible and by the use of air. Artificial respiration has been produced for centuries by the expansion and contraction of the thoracic cavity by stretching the musculature of that region. The methods accepted as best until recently are the Sylvester, Schafer, and Howard. These methods, while they are and have been generally efficient, have not been uniformly successful. If any rigor of the chest walls is present the methods
are fruitless, but if conditions are right they can and will produce a semblance of respiration which may be productive of good results.

Let us consider for a moment the means by which the movements of the arms or musculature produce respiration. The lungs depend, in the chest cavity, from the trachea much the same as a chandelier hangs from the ceiling. The lung tissue itself is in no way connected with the chest walls except by the pleura. When the chest walls are raised by drawing up the arms, the cavity is made larger and allows the lungs to receive air, because of a partial vacuum formed therein. If this vacuum is not created in the lungs themselves, very little, if any, air can enter. Even if a vacuum is produced, only a small amount of air will find its way into the lungs. To remove this air, pressure is applied to the chest, and, after an interval, the movements are repeated a certain number of times per minute.

A consideration of the late method of artificial respiration produced by the pulmotor shows that a true respiration takes place. Oxygen is forced into the lungs under pressure, and is afterward sucked out. This alternate movement is productive of an automatic institution of respiration. The pulmotor, however, has its limitations and objections. First, the apparatus is too heavy and cumbersome for one man to handle or carry with him. Second, none but Drager cylinders, fitted with Drager valves, can be used on the apparatus, thus precluding the possibility of using any oxygen in any cylinder that may be handy. Third, when the pressure of oxygen in the cylinder goes below about seventy to seventy-five pounds per square inch, the apparatus will not work, and operations must then be stopped until a new cylinder can be put in place. Fourth, the oxygen cylinders must be returned to the Drager Company for refilling, or sent to but one other firm of which I know, the Standard Oxygen Company, of New York. Fifth, the initial expense of the machine is great and the cost of operation is excessive; it averages about six to eight dollars an hour to operate. Sixth, and finally, the use of pure oxygen to produce respiration is objectionable.

While oxygen is the life giving substance of the universe, it is at the same time a life destroyer, as I shall point out later. Oxygen, to the extent of eight per cent, is required by the normal being to properly oxygenate the blood, and so sustain life. An amount in excess of that is practically useless, for it produces a slowing of respiration—for the human mechanism automatically takes from the air the necessary amount of oxygen by regulating the number of respirations demanded by the presence or absence of oxygen in the air inhaled. The slowing of respiration is due not so much to the excess of oxygen, as to the diminished amount of carbon dioxide in the blood, which condition is brought about by the excessive washing and oxygenation which removes by force practically all traces of the carbon dioxide and substitutes oxygen therefor. At first glance the removal of the carbon dioxide may seem beneficial. It may be thought that this is the desired end. If you are of this opinion, permit me to ask, Why do we breathe? Doubtless, many will remember that this question was well argued by the profession a few years ago. Numberless theories were advanced, of which but one stood the test. The final conclusion was, in substance, respiration is due to the irritation of the respiratory centre in the brain by the carbon dioxide content of the blood.

This conclusion is, indeed, a fact, as can be readily demonstrated by the inhalation of a mixture of carbon dioxide and air. The blood under normal circumstances has a content of from two to four per cent. of carbon dioxide, which is quite enough to carry on normal respiration. To remove that gas and to allow its place to be taken by oxygen, you can readily see, would produce a condition of acapnia or a cessation of respiration. If this is so, is it proper to administer a full percentage of oxygen for the production of artificial respiration? As I have said, the required amount of oxygen is about eight per cent. The atmospheric air contains about twenty per cent. oxygen. Atmospheric air also contains traces (to the extent of nearly one per cent.) of carbon dioxide; the balance of the mixture being mainly nitrogen. Would it not be better, then, to substitute for the oxygen just plain air, from which the requisite amount of oxygen may be taken, and if the necessary amount of oxygen cannot be obtained from the air at the normal number of respirations per minute, is it not possible to increase the number of respirations and so wash the blood more frequently, and thus attain the desired end? Is it not better to use the air, the natural medium, if for no other reason than for its content of carbon dioxide, which, by its property of causing respiration, will institute that function with less shock to the organism?

After a consideration of the objections and disadvantages of the pulmotor it occurred to me that an apparatus embodying but few of those disadvantages was possible. The apparatus shown is the result of that idea and many experiments. Its advantages may be enumerated as follows:

It is not cumbersome and heavy; in fact, it can be carried in a small case and weighs less than ten pounds. It does not depend upon any brand of oxygen, nor does its operation depend upon compressed gas. It is operated by hand and foot in the least tiring manner; both hand and foot can be changed without losing time or causing trouble. Its apparent initial cost is low, and it has no cost of upkeep. Finally, it makes use of air.

If it is desired oxygen may be employed, or a combination of oxygen with a definite proportion of carbon dioxide, but my own experiences suggest the use of atmospheric air of which there is always a plentiful supply.

The technic follows: With the patient lying down, the shoulders are raised by means of a pad, so that the head falls well back. The mouth is opened and a prop or gag placed between the jaws. False teeth or other loose articles are removed from the mouth. Grasp the tongue and draw it, even strain it, well forward, pulling it as far as it will go. Pass the finger down the throat and swab out any mucus that may be present, and draw the epiglottis against the base of the tongue. The tongue, being held as well forward as possible, the mask is adapted to the face. With the tongue between the mask
and the chin, and held firmly in place by a piece of gauze, strap the mask to the face; it must be very tight, so that no air may leak in or out.

These details having been observed, the mask is connected to the valve mechanism by a piece of rubber tubing from eight to twelve inches long. The valve mechanism is connected by more tubing to a pump or bellows of some description.

The bellows I use is the best I have been able to find thus far. I would, however, prefer a much smaller pump, but up to date I have been unable to find one. All connections being well made and tight, the bellows is pumped and air forced along the tubing through the valves into the lungs. By pressing down on the valve stem, the air in the lungs is forced out into the atmosphere by the elastic pull of the lung tissue. The valve stem is allowed to rise, and air is again admitted to the lungs.

The raising and lowering of the valve stem controls the number of respirations allowed per minute. On the valve mechanism is found a safety valve which controls the pressure of air. When the pressure of air in the lungs reaches a predetermined point, as set for on the index, this valve allows the excess air to pass into the atmosphere, and thus keep the pressure down to where it can do no harm. This is all there is to the machine.

For demonstration purposes, I use the pharyngeal tubes, which are placed with all the precautions observed in fitting the mask. With the tongue well forward and the epiglottis raised, a tube that is slightly larger than the pharyngeal opening is passed down so that the beveled end of the tube comes opposite the glottis or laryngeal opening. Held firmly in place, with the tongue well forward, the jaw is brought up against the tube and made fast. The final precaution to be observed is to keep the air from the stomach and intestines. This may be done by either of two methods, both of which are effective. First, by pressure on the upper abdomen by placing a weighted pad thereon or by pressing upon it, or, second, by pressing upon the cricoïd cartilage, thus compressing the soft esophageus between the cartilage and the spine.

It is noteworthy that the apparatus is applicable to all cases in which the respiration is impaired. The following merely suggests the cases in which the respirator may be of help.

Poisoning: By aconite and its derivatives; alcohol; acetanilide preparations; acids and acid fumes (nitric, natrium, etc.); amyl nitrite; benzene; belladonna and its derivatives; carbolic acid and similar drugs; chloral; chloroform; cocaine and its analogues; conium (hemlock); chlorates; carbon disulphide; ether; gelsemium; hydrocyanic acid and the cyanides; hyoscyamus; gases—acetylene, coal, marsh, pit, illuminating, etc.; nitrous oxide; nitrobenzene (oil of nitrobenzene); nitrates; opium and its preparations; physostigmine; petroleum products; snake bite; staphisagria and larkspur; sulphuretted hydrogen; strychnine and similar drugs; sulfonal, veronal, trional, veratrine, etc.

Drowning: electric shock; anesthesia; obstetrics, injuries affecting respiration, and all cases demanding artificial respiration.

With this apparatus I have caused the heart to beat in an animal that had been dead, or to put it differently, whose heart had ceased beating for as long as twenty-three minutes. This occurred in but one case out of 163 experiments. I have, however, instituted the heart's action in several cases in which the heart has not pulsated for periods as long as five minutes. But, that the reader may judge for himself, a report of the experiments I have made is appended.

The total number of experiments was 163: of which seventy-one were on dogs, sixty-eight on cats, one on a rabbit, and twenty-three on guineapigs.

Death was produced in fifty-two cases by chloroform, in forty-seven cases by carbon monoxide (illuminating gas), in thirty-three cases by curare, in sixteen by ether, in five by nitrous oxide (to asphyxiation), in five by drowning, and in one by ammonia.

The action of the respirator was positive in all cases, inflating and deflating the lungs perfectly.

The heart action was instituted in fifty-two cases, of which twenty-one cases did not institute normal respiration, but thirty-one cases responded well.

Of the thirty-one animals, fourteen required to be killed, nine subjects died (eight of these had been killed in the first instance by curare), and eight animals are or were, when heard of last, alive and happy.

The death period ranged from a few seconds to twenty-three minutes, with an average period of 4.23/31 minutes each.
All but thirteen animals had had their chest walls cut away, exposing the heart and lungs (it was because of this cutting that the fourteen mentioned above were killed after the experiment was finished. Of those alive, three had been killed by gas, three by chloroform, one by ether, and one by nitrous oxide.

Of the thirty-one cases in which life was restored, six had been killed by gas, nine by curare, eight by chloroform, two by drowning, three by ether, and three by nitrous oxide.

Several experiments have been conducted on cadavers, to show the positive action of the apparatus; and this was demonstrated to satisfaction.

I do not wish to be understood as asserting that this apparatus will raise the dead, but it will positively raise the dying to life if respiration can do it. The machine cannot do the impossible. It cannot do more than respiration can accomplish, and that is all I claim for it.

2105 Seventh Avenue.

CAESAREAN SECTION WITH HYSTERECTOMY IN CASES OF POSITIVE INFECTION.

By J. F. Baldwin, A. M., M. D.,
Columbus, Ohio,
Surgeon to Grant Hospital, etc.

At the present time there is among obstetrical surgeons some difference of opinion as to the best treatment of a patient in the presence of undoubted sepsis, with a viable child, and a contracted pelvis. Bumm, who represents the extreme, lays down the rule that the child should be delivered by perforation in all cases of contracted pelvis where fever is present and bacteria can be demonstrated. Peterson (American Journal of Obstetrics, lxxv, No. 2, 1912) says that in conditions of undoubted sepsis the only course to pursue “is to perforate the child, living or dead, and extract from below. Craniotomy may not save the life of the mother, for in such septic cases it carries with it a mortality of ten or fifteen per cent., but at least it gives the mother an infinitely better chance than can any variety of Caesarean section.” In cases of only probable infection, where there have been repeated vaginal examinations, and some attempts at delivery, but no fever and no foul discharge, Peterson advises the Porro operation, with dropping of the stump covered by peritoneum.

In response to a few personal letters of inquiry as to the proper treatment of a patient with undoubted sepsis and a contracted pelvis, but with a living child, I received replies as follows: Gustav Zinke, Cincinnati: “Vaginal removal of child. Abdominal hysterotomy contraindicated.” Asa B. Davis, New York: “Craniotomy, I have been tempted to perform Caesarean sections upon such patients, but the results are almost invariably bad for mother and child.” C. S. Bacon, Chicago: "Caesarean section no longer possible. Craniotomy." J. Whitridge Williams, Baltimore: "Craniotomy. Caesarean section only after the great risks associated with it have been explained to the parents and accepted by them. In that event I should remove the entire uterus after delivery.” Elice MacDonald, New York: “Would consider no mode of delivery save by the pelvic route.” Joseph B. DeLee, Chicago: “Craniotomy, Caesarean section, even extraperitoneal, not justifiable.” Barton C. Hirst, Philadelphia: "Vaginal delivery, or extraperitoneal Caesarean if the parents are particularly anxious for the life of the child." E. P. Davis, Philadelphia: "Porro operation." J. Clifton Edgar, New York: “Craniotomy.” The hypothetical case given to each of the physicians mentioned above was one which will be reported a little later in this paper. Several of them would have attempted the delivery with forceps after correcting the malpresentation, but one only favored any form of Caesarean section. E. P. Davis, however, has had excellent results with Caesarean section followed by removal of the uterus (Porro), and he recommended that procedure in this instance.

The problem presented by the case seemed to be a straight surgical proposition. Here was a live child, with no evidence that its vitality was particularly depressed. Delivery alive through the natural passages was impossible, while that delivery would have resulted in extensive lacerations which would have greatly increased the danger to the mother. To remove the child by Caesarean section would give it every opportunity to survive, while the removal of the infected uterus would greatly increase the mother’s chance of overcoming the infection. The added danger to the mother would be chiefly from the possibility of infecting the peritoneum from some escape of uterine contents. It seemed to me that this danger could be reduced to a minimum by opening the uterus only after it was outside the abdomen, surrounded with towels and sponges, and after the free use of the tincture of iodine, in the antiseptic powers of which, from long experience, I have become a firm believer.

The result in the case reported does not necessarily mean anything, as it might be merely the exception which would prove the rule, but the prevailing pessimism of operators in regard to Caesarean section in septic cases has never impressed me as being surgical, but rather as a confession of inefficiency which should not be permitted to go unchallenged. Every surgeon knows that if we can diminish the amount of infection present in any given case, and remove the source of supply of that infection, we give our patient the best possible chance to recover. A rapid Caesarean section, therefore, with removal of the infected uterus, would seem to meet all the indications and, if we can prevent septic peritonitis, should give us the best possible results for the mother, while giving the child its only possible chance. By using the tincture of iodine freely in the field of operation, and deluging the interior of the uterus with it as quickly as the fetus is removed, applying it thoroughly to the cervical canal before amputating the uterus, it seems to me that the danger of septic peritonitis is reduced to a surgical minimum.

Some one, about a year ago, suggested that the use of iodine on the surface of the abdomen might result in intestinal adheresions with ileus, if by any accident the intestines came in contact with this.
Iodined surface. I have seen only the one report, but that report was widely copied and has perhaps deterred many surgeons from using iodine as freely as they otherwise would. The report seemed to me unreasonable, and indicated that the operator had generalized from a single case. I have used iodine over the abdominal surface in several thousand cases; I have used it freely in the pelvis in cases of pelvic infection, and use it constantly over the field of operation in making intestinal anastomoses and gastroenterostomies. Thus far I have had no case of ileus following its use, nor have I had any cases in which postoperative adhesions were more in evidence than without it. I think, therefore, the danger from its use may be regarded as practically nil.

The second case reported is added merely as corroboratory of the advantages of prompt removal of the source of infection. Many similar cases could have been reported, but this one was added because it occurred in such close juxtaposition to the other, and was so marked an instance.

Case I. Mrs. B., aged twenty-nine years. She was taken in labor at full term with her first child September 7, 1912. (She had had an early miscarriage some three years before.) The pains were not very efficient, and the waters broke two days later. As it became evident that there was some serious condition preventing delivery, the patient was brought to Columbus on the afternoon of the 13th, where I saw her in consultation two or three hours later. Forceps had been applied, but they would not lock. The pains had entirely ceased. The patient was exhausted. Pulse 130, temperature 104.6° F. Examination showed the soft parts fairly dilatate. The child was large and presenting by breech, where a large caput succenturiatum had formed. The fetal heart sounds were positively differentiated, so that it was determined that the child was alive. I advised an immediate Cesarean section in the interests of the child, and a hysterecctomy in the interests of the mother. This proposal was accepted and at once carried into execution. The operation was made in the usual way, except that, contrary to my usual custom, I made a low incision and brought the uterus entirely out, packing towels around and behind it to protect the peritoneum from any possible irritation from the uterine contents. The child was a male and, as previously determined, unusually large. It was delivered without event. A hasty examination of the interior of the uterus showed a large patch of necrotic, but evidently necrotic, tissue corresponding to the point where the fetal head had been resting upon the pubic bone. The uterine cavity was then flushed with tincture of iodine which ran down through the cervix and out the vagina. A supravaginal panhysterectomy was then completed in the usual manner, except that one ovary was saved. The appendix was removed on general principles. The incision was closed without drainage.

The child was promptly resuscitated, but presented the usual monstrous appearance of a brow presentation. The temperature of the patient quickly fell to normal, and the convalescence of both was absolutely uneventful, and both were alive and well, July, 1913.

As an illustration of the advantages of hysterectomy in some of these cases of infection, I report the following case, particularly as the operation occurred on the day following the Cesarean section:

Case II. Miss K., aged fifteen years. Had been delivered of her first child after an entirely normal labor at the McMaster Crittenden Home, September 6th. Her convalescence was entirely normal for seven days, and she had abundant breast milk for her baby. On the morning of the 13th, without assignable cause, her temperature was found to be 102° F., then increased rapidly of 104° F., and upon this a feeling of discomfort. In the evening her temperature was 103° F. On the morning of the 14th it was 104° F., and in the evening 106° F. At that time I saw her in consultation.

The patient looked profoundly septic. The uterus was not undergoing quite normal involution, but was in fair shape, though quite tender. There was no odor to the discharge. I advised hysterecctomy as the treatment which would be most apt to promptly get rid of all source of infection. This was concurred in, and the patient was brought to Grant Hospital. A supravaginal panhysterectomy was made that evening in the usual way. One ovary was saved because of the youth of the patient. The appendix was removed. The incision was closed without drainage. Iodine had been freely used in the cervical canal before closing the cervical flaps and overcasting the peritoneum.

During the operation it was noticed that some of the veins in the right broad ligament were plugged, but there was no evidence of any pus at these points. On opening the uterus, the placental site was found to be the seat of an acute infection, which had resulted in quite deep penetration of the tissues.

The patient's temperature promptly fell to normal, and her convalescence was entirely uneventful.

115 South Grant Avenue.

THE APPENDIX AND SOME OF ITS DISEASES.

By Helen Hughes Hirsch, M. D.
Mankato, Minn.

"The beginning of philosophy," says Epictetus, "is the observing how men contradict each other." This spirit of contradiction was remarkably wanting in the early days of medicine, though minor bickerings occurred to a degree that would make one of the ancients feel perfectly at home at a county society or physician's club meeting of the present day. Without laying claim to "contradiction," which is the very spirit of progress, this paper will attempt to follow the fragmentary history of the appendix with a view to find some logical basis for its disease, and the treatment thereof.

In the days of Galen, and before, no such organ as the appendix vermiformis was described, but for that matter the whole intestinal tract was passed over with the simple classification of "intestina crassa" and "intestina tenua"—the thick and the thin intestines. Galen flourished in the second century, and from his day until about the beginning of the sixteenth century very little more was done for the science of medicine than to preserve his teachings; every school and every individual investigator exerting its or his energies to make facts as they found them conform to its or his writings. The shackles which Galen forged about the science of medicine were loosened by Vesalius in the first half of the sixteenth century. This notable scientist rose up and contradicted the hoary teachings of the great master. In his zeal he went as we now know too far, for he asserted that Galen was no great "master" at all, and that his works showed such ignorance as was proof positive that he never dissected a human body, but made his deductions from apes. With Vesalius came a revival of the actual study of anatomy, and although the intestines received very little attention, the appendix vermiformis was described and classified as a part of the "intestina crassa."

It is curious that so little was done toward the study of the intestines in the early days, for their appearance must have been quite familiar to the
priests who offered sacrifices, because their duty was to inspect them for omens, and observe that they were in a healthy condition; for the gods supposed to abhor disease in any of their victims. War also of the kind that was waged in early days must have often exposed them in the living human subjects, and the custom of embalming afforded the Egyptian priests, who were also the physicians, great opportunity for their study, as the intestines were removed from the body cavity in order that it might be filled with spices. Yet no advances seem to have been made in their study. As a matter of fact, the intestines were looked on merely as tubes for reception of waste matter, and quite beneath the notice of the scientist. Cicero, in his De Natura Deorum, informs the reader that "he knows the alimentary canal, but from motives of delicacy omits the details," and Boerhaave, writing in the seventeenth century, prefaces his chapter on the expulsion of the feces in the Institutes and Comments with this apology, "now we come to a nasty, but necessary part of the business," though he traced the food through the upper part of the tract apparently without shame. This feeling as to the inferiority of the intestines may account for the neglect that was their portion until they exalted themselves by disease to that "bad eminence" which they occupy at the present time.

Vesalius died in 1564, and a little more than a century afterward, Boerhaave was born (1668). During the period between Vesalius and Boerhaave many independent searchers sprang up, some of them of such transcendent genius that their light shines even to this day. There were Eustachius, the contemporary of Vesalius, whose beautiful anatomical plates are still the delight of the anatomist's heart, and which he was, alas, too poor to have the joy of seeing published in his lifetime; Fallopia, the pupil of Vesalius, and Varolius, the physician of Gregory the Thirteenth, whose name lives in the "pons Varolii." Then, there was the priest Servetus, whose deplorable death at the stake set back the discovery of the circulation of the blood at least half a century; Harvey, who described this in 1600, and Fabricius, his teacher, whose observation of the valves in the veins of the lower extremities must have been such an aid to his brilliant pupil.

It was about this time that an interest began to be manifested in the intestines, delicately at first. "Wie die Katze um den heissen Brei." They began with the mesentery, and the upper or more honorable parts of the tract. It should be remembered that there was already some work done on the mesentery as early as 270 B.C. for Erasistratus and Hierophilus described the white vessels, or lacteals, in the living kid, and the receptaculum chyli and thoracic duct in the horse, named the twelve inch portion of the intestines and noticed the likeness of the convolutions of the jejumum to those of the brain. In 1637 Higomore was able to distinguish between the lacteals and the mesenteric veins. Some time afterward Olaus Rudbeck distinguished the lacteals from the lymphatics, describing for the first time the latter order of vessels. In 1652 this young anatomist traced the lymphatics to the thoracic duct and hence to the subclavian vein, in a public demonstration before Christina, queen of Sweden. It seems to have been a custom of those times to make public demonstrations of any newly acquired knowledge, as if a victory that concerned everybody had been won over ignorance. This practice did not fail to bring glory to the individual, but was not without its dangers, for Wirsung was eminently assassinated on the evening of the day upon which he demonstrated so beautifully the pancreatic duct. Peyer and Brunner were at work also about this time, and with the aid of the microscope, that Leeuwenhoek was bringing to a high stage of usefulness, they opened up new fields to both the anatomist and the physiologist. Then Ruysch was pursuing his methods of research by injecting the hollow chambers of the body, so that it was said of him that "nothing in the human economy escaped his pipelette."

The advent of Boerhaave into the scientific world marks an epoch in the development of knowledge concerning the appendix, for he was the first to give it the dignity of physiological utility. His description is confined to a few lines, and his physiology is incorrect; yet his teachings are of such a nature as to make them highly important. Boerhaave himself is a striking figure in an important era. He was professor in the University of Leyden when that institution was at the height of its glory. His fame drew students from all parts of the world. Peter the Great, of Russia, spent some time in his classes. His contemporaries were Valsalve, Suntorini, and Morgagni. Von Haller was for some time his pupil, and he collaborated with the brilliant young Nuck, of whom he writes: "I have seen him more than a hundred times spread out the mesentery on a table, and, with a steel tube inserted into the least of the lymphatics, demonstrate the whole system." Boerhaave's standing, and his place in the scientific world, is gone into here in order that due weight may be given to his teachings, and that an ignorance of his subject may not be suggested as an excuse for the contradiction that appears between his writings and the facts of the present day.

Boerhaave first mentions the appendix to contradict his master, Vesalis. "We cannot agree," he says, "with the modern anatomists, Vesalius and others, that the appendicula vermium formis should be reckoned one of the large intestines." Again, he says: "There is a considerable quantity of feces found in the large intestine of the fetus and in the appendix, which at the time of birth is found full of feces representing the juice of poppies, and which is called meconium." With Boerhaave, anatomy was the handmaid of physiology, as it was with all the older writers up to the time of Winslow, and though he confines himself to a few words on the anatomy of the appendix, he goes at length into a fantastic explanation of its physiology. This is his anatomy of the part: "The reservoir or diverticulum of the cecum is furnished with a small vermicular appendix or little intestine." This meagre account is reinforced by a note which says: "This is a small slender process of the cecum, arising usually from the bottom or sides, and at some distance from the colon, in that
part which is opposite to the ilium. This process, or membranous bag, is furnished with glandular tissue, which discharges mucus to the feces. Then follows his physiology: "The appendix is larger in the fetus, which serves to increase the space destined for the reception of the meconium, . . . but when the feces are accumulated in these parts to such a degree that they cannot easily be con-
tained, by distending and irritating the intestines, it occasions pain and causes the infant to struggle; whereby the natural birth is promoted." To go back to his anatomy, the term membranous bag is hardly descriptive of the appendix of the present day. As a clue to the changes that have taken place in the appendix, let us follow Boerhaave's description of other parts of the intestine: "Follow-
ning the Ancients," he writes in Institutes and Com-
ments, "we call that part of the colon the ce-
cum, which is large and globular at its end or be-
inning, and so capacious as at times to be equal to
two span (?), and in it the feces are collected as
they slip through the ilium." Now a span is a
unit of measurement based on the distance between
the tips of the thumb and little finger of the ex-
tended hand, and is reckoned at nine inches. A
cecum of the present time measuring eighteen
inches would be very extraordinary indeed.

Boerhaave's description of the duodenum also
affords matter for thought. In his lectures on an-
atomy, while teaching that science in the Univer-
sity of Leyden, he says, "The duodenum, the first
part of the small intestines, has this peculiar to
itself, that it is disposed in a straight direction."
There is a note appended, which reads, "It is re-
markable that this is the only part of the intestine
with the beginning of the jejunum, that is dis-
posed in a straight course, all the rest being sur-
prisingly convoluted into various turnings and
windings." Further, he states, "The duodenum
arises at the pylorus and terminates at its incurva-
tion immediately below the insertion of the biliary
duct: . . . there are few instances of the biliary or
pancreatic duct opening into the upper part of
the duodenum." Here he cites the cases of rav-
eous fishes and birds, such as the ostrich, whose
bile ducts open directly into the stomach. His de-
ductions are not the result of a cursory examina-
tion, for he can describe minutely how the bile duct
passes 'first a little way between the external and
muscular coats, and then for about an inch between
the muscular and villous,' and it does not escape
him how "the fibres of the muscular coat serve for
valves to prevent regurgitation from the intes-
tines." In speaking of the muscular coats of the
intestines he says: "There are three strong liga-
maments detached from the appendix on each side
throughout the length of the colon, which contract
it like so many muscles and terminate in the rec-
tum. These ligaments are six times shorter than
the colon itself, so that on separating them from
the intestine it becomes much elongated, thinner,
and narrower."

In comparing these statements with the facts of
the present day, we are forced to the conclusion
that either Boerhaave and other anatomists of that
time were very careless observers, or that the an-
atomy of the parts has undergone considerable
change even in the past three centuries. The ap-
dex certainly seems to be contracted, since Vesalius classified it with the great intestines, or
even since Boerhaave described it as a "mem-
branous bag." The muscular fibres of the appen-
dix are arranged more like those of the stomach
than the intestines, and its mucous surface is still
supplied with glands. The muscular fibres sug-
gest a capability for emptying itself, which presup-
poses that it was used as a receptacle of some kind,
such as the stomach, while the glands suggest some
form of secretion analogous to that of the stomach,
where the main use of the mucus glands is to pro-
tect the walls of the meconium from the highly irri-
tating product of the oxidative cells. If the stomach
were to become atrophied we would expect such
an order in its recession, that is to say, the dis-
appearance of the glands whose secretion assists in
digestion pari passu with a failure of the supply of
material to be digested, with a persistence of the
mucous or protective agent.

If the appendix ever was an organ connected with
digestion it is quite reasonable to suppose that
in some cases secreting glands still persist that
under stimulation are capable of producing a sub-
stance as irritating, and poisonous, as the hydro-
chloric acid of the stomach—indeed, in their atrophying, perhaps many times more irritating.
The effect of this fluid, poured into the empty
and contracted appendix, would be just such as we
see in those cases of fulminating appendicitis where
the reaction is intense, and no germ has been re-
covered from the lesion, except those native to the
intestines, and to a certain degree harmless. It is
a bold, but nevertheless true expression, that the
ordinary case of appendicitis, under the present
methods of treatment, is a benign disease. Even
with rupture and abscess formation there are com-
paratively few deaths, but in spite of this fact we
must acknowledge that every once and a while we
are confronted with cases that die before we have
really settled down to any plan of treatment. These
fulminating cases can be compared with great
profit to a condition that gives rise to almost the
same set of symptoms, and which in fact is some-
times mistaken for them, that is, perforation of
the stomach or duodenum. The sudden onset, the
shock, the small, irregular pulse, the pain and rig-
idity in the hypochondrium, as the acid stomach
contents trickle downward, strongly simulate a
severe appendicitis. Even when the patient comes
to operation, except the perforation has occurred
while there is food in the stomach, so that particles
of it may be seen free in the abdominal cavity,
the error may not be discovered, for the grayish
fluid may be mistaken for pus, while the deep suf-
fusion of the intestines and the appendix seems
to confirm the diagnosis—so the appendix is removed,
and the patient left to his fate.

Now if we look on the appendix as a vanishing
organ of digestion, having its utility in some previ-
ous age, when the sustenance of the human family
was of such a nature that it required a longer
time, and a somewhat different apparatus to digest,
and that this atrophying organ is still capable of
producing under certain stimulation a digestive
fluid, we can see immediately the sequence—death
from a strongly irritating chemical poison. If these deductions are correct, there is only one method of treatment for such cases, and that is immediate removal of the appendix. It is a well known fact that extraordinary results have followed in almost moribund cases where sluicing with warm saline solution was resorted to, following removal of the appendix, and even large quantities left in the abdominal cavity. This would be a logical treatment where a chemical irritant was the cause of the condition, though contraindicated in the ordinary cases of bacterial infection.

CARBON, OXYGEN, HYDROGEN GROUP, PLUS NITROGEN OR NONNITROGENIZED AND NITROGENIZED FOOD.

By J. C. Densten, Ph. D., M. D., Scranton, Pa.

Food, or aliment, as distinguished from condiment, means, in the scientific sense, any substance that, being taken into the body of animal or plant, serves through organic action to build up normal structure or supply the waste of tissue. Liebig classifies food into (1) nitrogenized elements of nutrition, or those that serve for the nutrition of organized tissue—flesh formers; (2) nonnitrogenized elements, or those that are consumed in respiration—heat givers. Therefore, we have, from the nitrogenized and nonnitrogenized elements, not only tissue building material, but also fat forming elements, each belonging to the carbon, oxygen, hydrogen group; one a carbohydrate; the other a hydrocarbon. These elements exist, in some form of combination, in almost every substance used as food, and, in the process of digestion, become subservient to the function of organic action.

To this carbon, oxygen, hydrogen group belong all substances containing the elements of starch, and it is confined to the vegetable world; potatoes and the cereals being the most active source of production. All foods containing starch we term carbohydrates; but carbohydrate food will not build up or maintain life indefinitely without the combining effort of the added element, nitrogen. We must therefore have, not only carbohydrate food, but nitrogenous food also; and since nitrogen is found largely in meats, eggs, fish, etc., we have learned to partake of mixed foods, containing both starch and nitrogen.

Now, what is the modus operandi within the animal economy, as the result of this mixed diet? Let us first inquire into the chemical changes necessary to maintain life and produce tissue. Starch and nitrogen, given per se, will mean nothing toward sustenance until the animal economy has converted these elements into tissue building material. Metabolism is the all important factor in the maintenance of life and health. Heat and energy become absolutely necessary in order to convert the nitrogenous or protein elements into proteins and thence into tissue and fat. In order to get this heat and energy our body burns carbon, and thereby gets the heat, while the energy is supplied, as the result of combustion, by the water contained in the starch elements. The starch first splits into glucose, or starch sugar, \( C_6H_{12}O_6 \); then into alcohol, \( C_2H_5OH \), this being the most convenient and available form by which the carbon can be separated from the water (\( H_2O \)) and utilized. The nitrogenous substances, or proteins, are converted into proteids, and thence into tissue building material, by the heat and energy contained in the carbohydrates, the waste being eliminated as carbonic acid anhydride, via the lungs in our exhalations. At the same time there is a constant supply of oxygen entering the body by inhalation, to reoxygenize the venous or carbonized blood, and convert from bile to red the blood, which is carried again to all parts of the animal system, to maintain life and health.

An animal while growing needs much more food than after maturity. The necessary amount of food after maturity is just sufficient to resupply the waste. Any food above this required amount will clog the system, or, if the animal be strong and healthy, may then convert the surplus into fat, and store it away in the body as a hydrocarbon. This is a wise provision of Nature, for when one is overtaken by disease this fat becomes a storehouse of food which will lessen markedly the waste caused by fever and friction, even while the patient remains unconscious or is unable to eat or assimilate ordinary foods.

Many medicinal agents serve to take the place of food. Why does strychnine \((Ca\text{H}_3\text{N}_2\text{O}_4)\) act as a tonic? Because it becomes a food. It contains carbon, oxygen, hydrogen, and nitrogen sufficient to make it a true "flesh former," and thus is a source of Liebig's "nitrogenized elements of nutrition." Most of our drugs which soothe and quiet pain are, in a sense, food. Pain is often a nerve calling for food. Take atropine \((C_{17}\text{H}_{25}\text{NO}_3)\) and hyoscyamine \((C_{17}\text{H}_{25}\text{NO}_4)\); these are isomeric, with practically the same physiological action, are wonderfully effective in disease, where indicated. And how do they alleviate and cure? Just by resupplying that something which is necessary for normal health. Then they likewise must become food and furnish Liebig's "nitrogenized elements of nutrition."

Morphine \((C_{17}\text{H}_{19}\text{NO}_3 \cdot H_2O)\) and cocaine \((C_{17}\text{H}_{19}\text{NO}_4)\) are isomeric and belong to the carbon, hydrogen, oxygen group, plus nitrogen, and hence become a food. All the alkaloids of opium contain carbon, hydrogen, oxygen, and nitrogen, and must of necessity be classed as food. How well we know that patients may be kept alive for weeks and months by this artificial feeding. But while they become a food under restriction, they also become irritants and destroyers when unrestricted, and this assertion is applicable to all ordinary food products, outside the realm of drugs and chemicals.

Now alcohol has its uses and also its abuses. We cannot live and have our being without alcohol in our system. We have seen that all the starches are converted into alcohol before work on the rehabilitation of the organism can begin. But this is no excuse for abusing it, as many do. We have also tried to show that any food becomes an irritant when taken in excess, or above a legitimate
demand. We see diabetics suffering from glycosuria and glycoehmia, and we delve into our textbooks and find—nothing. We read current medical literature on the subject, and one authority tells us to take away the carbohydrates, while another tells us to feed carbohydrates "good and plenty," and each is sincere in his advice. Now they cannot both be right. It is axiomatic that if withdrawing the carbohydrates from a diabetic patient would benefit and cure him, then administering the carbohydrates "good and plenty" would not benefit him, but kill him. Why cannot science and reason come to our assistance? Why does a diabetic pass sugar? Because of faulty metabolism. He is not able to split the sugar into alcohol in his system. But why? It is up to the physician to find out. This much is certain, however, that if you withdraw the carbohydrates the patient will feed on himself until all his fat has been consumed, and then he will die. I give all my diabetics carbohydrates, "good and plenty," with a sufficient amount of alcohol to convert the nitrogenous food into tissue building material, and thus sustain and maintain their equilibrium and avoididupoius. The patient must have a certain amount of alcohol in his system, and it is the physician's duty to see that he gets it, either by remedying the metabolism by treatment, after ascertaining the etiology of the disease, so that a normal condition will prevail, or else by supplying it direct. Alcohol will always benefit a diabetic, for without it in the system he cannot convert the nitrogenous substances into tissue building material, and so will lack sufficient food to sustain life.

If this be true, why should those in advanced age, with falling off of youthful virility, continue to eat the carbohydrates in as great quantities as in youth? Why not swallow a raw egg and a tablespoonful or two of good old rye and give the stomach and system a rest? Here we get the same result as from stuffing with potatoes, cereals, and meats, and the results are all that are necessary. As a rule we eat too much. We need but enough to resupply the waste and no more, if we are to remain healthy after fifty. Arteriosclerosis will find us sooner from gluttony, and embolism and thromboosis be more likely. One who has been temperate up to the age of fifty years may not fear to indulge in a tablespoonful or two of whiskey daily. Not many people become drunkards after fifty. There comes a time when we need a stimulant, and one is embarking on a longer life who knows just when and how much to take. Alcohol is a carbohydrate and carbohydrates are food. But alcohol taken in excess becomes an irritant; it should be taken, like other foods, only when necessary, and then with restriction. Young people do not need to drink alcohol. They have power to convert the starches sufficient for the necessary up-building of their bodies within the zone of health.

If we would prolong the life of a patient, he must be fed. Food then becomes essentially important, in preserving the continuance of animal life. There are many ways to administer food. Any substance containing both a carbohydrate (C.H.O.) and nitrogen becomes food when assimilated by the animal economy. But such substances should be administered in the most concentrated form in order to become assimilated with the least possible exertion on the part of the patient's system. So we conclude that of the carbohydrates, alcohol becomes the most available concentrated form where quick nutritive effect is desired. For prolonged tonic muscular effect strychnine stands preeminent, and may always be relied upon to take up the slack of a weak heart. In alcohol we have a nonnitrogenous food, a heat giver, which is consumed through the respiration. In strychnine we have a nitrogenous food which furnishes tissue building material, and hence is a flesh builder.

311 Spruce Street.

AN UNUSUAL CASE OF SEPTICOPYEMIA.

By W. B. Coffey, M. D., G. R. Carson, M. D., and W. T. Cummins, M. D.,
San Francisco, Cal.

N. E. N., aged twenty-eight years, American, baggage man, was admitted to Southern Pacific Hospital, November 14, 1912. Family history negative. Previous history: Usual diseases of childhood; typhoid fever in 1902; denied venereal infection. Present illness began two weeks before admission, when, after being chilled, he was seized with thoracic pains, cough, and dysuria. Headache developed and all symptoms increased in severity.

Examination: Well nourished young man; pulse 84; temperature 102.6° F.; respiration 24; tongue heavily coated and breath foetid. Left buttock showed a large boil with considerable edema, redness, and seropurulent discharge. Over lower right side of thorax dulness, increased tactile fremitus and vocal resonance, and friction rub. Over upper thorax, moist crackling rales. Over lower, left side flatness, much decreased voice and breath sounds, and coarse friction rub; many fine moist rales over upper lobe of lung. Examination of heart and also genitah, negative.

Uranalysis: November 14th, negative; November 28th, albumin +, granular and hyaline casts; epithelium and leucocytes; agglutination reactions, Bacillus typhosus, negative. On admission, leucocytes, 16,200; systolic blood pressure, 108 mm., Hg.

The physical signs of pneumonia persisted; restlessness and tremors increased; periods of stupor developed. Therapeutics was chiefly symptomatic in character, including local dressings, normal salt solution, strychnine, etc. A few days before death a soft systolic, nontransmitted, aortal cardiac murmur was heard. Abscesses were then noted over the left shoulder and right elbow. Diarrhea developed three days before death, and at one evacuation, a large clot of blood was seen. Complained of severe pain in both arms. Deafness appeared. Breathing was stertorous. Death occurred in coma December ist. Blood culture on admission showed Staphylococcus aureus in pure culture, and two weeks later the same organism was isolated. Put from the left shoulder and gluteal abscess showed staphylococi, as well as a few acid fast organisms from the latter location. Clinical diagnosis, pyemia; ulcerative endocarditis.

Post Mortem Record: Exterior of body showed no abnormality except shoulder, elbow, and gluteal abscesses. Peritoneum normal. Splenic weight 120 grammes; capsule normal; cut surface dark brown; follicles and trabeculae indistinct; at hilium a small anemic infarct; elsewhere a few, small, yellowish white, soft areas noted. Liver, 1,590 grammes; capsule normal; cut surface "nutmeg" and fatty changes; over capsular and cut surfaces numerous, yellow, firm, millet seed sized areas seen. Gallbladder apparently normal. Stomach and intestines moderately congested; in ileum numerous, yellow, elevated, firm, split pea sized areas; examination of Peyer's patches negative; mesenteric nodes enlarged and firm. Pancreas, 100 grammes, apparently normal. Left kidney, 230 grammes; capsular surface showed a few large yellow, softened.
elevated areas; areas of similar color and consistency, though smaller, seen in cortex and medulla; pyramids congested; left adrenal and ureter apparently normal. Right: kidney, 250 grammes and similar to left: right adrenal apparently normal, irregularly dilated throughout its continuity; no pus. Bladder apparently normal; left lobe of prostate showed abscess formation; testicles not examined. Upon probing gluteal abscess a sinus was found to extend to the ischiorectal region and over to wall of bladder, but not quite reaching the hip joint. Left pleural sac contained 400 c. c. bloodstained yellow fluid; a few recent adhesions at apex; lung, 250 grammes; along pericardial border of upper lobe a pea sized, soft, yellow, elevated area noted; basal congestion, and marked edema. Right pleural sac showed old adhesions at apex; lung, 700 grammes; a few soup bean sized, yellowish white, soft areas containing pus scattered throughout organ; consolidation at base; marked edema elsewhere. Pericardial sac apparently normal; heart, 370 grammes; numerous millet seed sized yellow areas slightly projecting on the pericardial surface of left ventricular wall; aortic, mitral, and pulmonary valves apparently normal; in auricle five mm, above free margin of tricuspid leaflets there was a thin, yellowish, definite edge to base of epicartilage, a pin head sized, yellow elevation containing pus; thyroid apparently normal. Brain showed a goose egg sized abscess, with ragged necrotic walls in the right occipital lobe, just beneath the meninges; elsewhere the tissues were congested, edematous; spinal cord not examined.

Histological Examination: Spleen, moderate capsular fibrosis, infarction, numerous polynuclear cell collections and necrosis; several bacterial masses (cocci); no amyloid degeneration. Liver, moderate cloudy swelling, passive congestion, and periacinar hemorrhation; several necrotic areas, as in spleen. Ileum, hemorrhages in mucosa and submucosa; a few cellular collections, as in spleen. Appendix, fibrosis of submucosa. Pancreas, post mortem changes. Kidneys, marked cloudy swelling; cell collections and necrosis, as in spleen; several bacterial masses; hemorrhages into tubules. Adrenals, congestion and hemorrhage. Prostate, one large and several small necrotic areas with cellular peripheries; many bacterial masses. Lungs, fibrosis of pleura; several large and small areas of necrosis and cellular collections; fibrosis and vascularization of alveolar contents in many places; some alveoli filled with polymorphs, fibrin, and proliferated endothelium; elsewhere emphysema, edema, and hemorrhages. Thymus, fibrosis of pleura; several large and small areas of necrosis and cellular collections; fibrosis and vascularization of alveolar contents in many places; some alveoli filled with polymorphs, fibrin, and proliferated endothelium; elsewhere emphysema, edema, and hemorrhages. Thyroid, two arteries showed intimal fibrosis and calcification. Rectus abdominis, polynuclear cell collections, but no necrosis; congestion and hemorrhage. Cerebrum, several cell collections with and without necrosis (right parietal lobe).

Bacteriological Findings: Cultures from spleen showed Staphylococcus aureus. Smears from abscesses of right elbow, liver, ileum, kidneys, and brain showed same organism.

Pathological Diagnosis: Abscesses of left shoulder, right elbow, spleen, liver, ileum, kidneys, prostate, mesenteric nodes, lungs, heart, epicartilage, and cerebrum; ischiorectal abscess; chronic perisplenic and amniotic infarction; acute paraspinal abscess and peritonitis; periaortic appendicitis; acute perineal and interstitial appendicitis; acute parapharyngeal nephritis; hemorrhage in adrenals; organizing pneumonia, emphysema, and edema; acute toxic arteritis (coronaries) and ulcerative tricuspid valvulitis; calcification of thyroidal arteries; acute myositis (rectus abdominis).

Remarks. This case presents several points of interest, viz., the typhoidal type of temperature, the intestinal abscesses, and the ulceration of the tricuspid valve without involvement of the left sided valves. The cerebrum, ischiorectal region, and lungs were suggestively primary foci. The abscesses of the gluteal and ischiorectal regions and lungs offer the most probable sites. The acid fast organisms suggest a tuberculous ischiorectal ab-

scess (chronic) independent of the pyemia, which, however, doubtless contributed materially toward extension into the gluteal region. The well defined organizing pneumonia changes associated with suppuration in the lungs indicate a primary croupous pneumonia and ulcerative endocarditis, and a terminal systemic distribution of the pyogenic organisms.

SOUTHERN PACIFIC HOSPITAL.

SOME REASONS FOR ADVISING NO DELAY IN OPERATING ALL FORMS OF HERNIA.*

BY JULIUS FRANKEL, M. D.,

New York, Adjunct Surgeon, Har M.ROHospital; Chief of Clinic, Surgical Department, Har M.ROHospital.

The term hernia in this little paper will have reference to organs escaping into openings or passing through the walls of the abdominal cavity, such as umbilical, diaphragmatic, inguinal, femoral, and ventral hernias.

In submitting my reasons for the early operation of hernias I do not care to discuss the kind of operation that is best for a radical cure, nor do I want to show preference for any particular kind of operation, as these procedures are so numerous, and almost all of them achievements of brilliant minds; each having its own special indication. Neither do I wish to discuss the skill required for its performance; nor will I even mention a single point in the methods of diagnosticating the presence of hernia. What I aim at in a general way is to condemn the so called truss wearing cure, and to urge that all hernias ought, as a rule, to be operated upon as soon as the diagnosis has been definitely established, even when only a small sized tumor can be felt, on the impulse of coughing or straining, in the inguinal, femoral or umbilical rings. Naturally, there are some contra indications, to operation, and these will enumerate later on.

A prominent surgeon once remarked, "Every person with a hernia wears his death robe." This statement is an exaggerated one, especially in modern times and in cities where surgical interference can always be obtained at any time. I would modify it by saying, "A person with a hernia carries a serious charge against himself, but can easily free himself of the same at will."

The patients suffering from hernia are of two kinds: (a) Those in whom surgical interference must be immediately instituted, because the life of the individual is threatened—such cases as strangulated, infected, incarcerated, and very large and irreducible hernias. (b) Those in whom operation can be delayed for a limited or reasonable period of time. In the latter class of cases the individuals are usually deprived of a great many of life's pleasures, health being impaired and the fear of the hernia's becoming strangulated at any time causing great uneasiness of mind and therefore serious hampering in the usual routine of daily life.

*Read before the Har M.ROHospital Clinical Society.
The continuous wearing of a truss is a misfortune that no young person likes, and ought not to submit to unless forced to do so by contraindications to an operation. I have made a careful investigation of various forms of trusses, and regret to state that I have as yet failed to discover one that would thoroughly fit, and perform the task it is designed for—by this I mean to say that the head or pad of the truss never thoroughly seals the margin of the opening of the tumor's point of emergence. It should be immovable and not press too hard, for undue pressure cuts off the circulation and innervation of the parts, which weakens the abdominal wall and in inguinal hernia is liable to injure the cord and testis. What I found almost without exception in people wearing trusses was, that the frame and head of the truss pressed too hard, so that the skin underneath was pale, numb, and imperfectly nourished. The fascia and muscles, I suppose, suffer similarly. The hernial tumor often comes out above or below the head of the truss, and, as a result of this mechanical irritation of the parts, pain is produced and a local inflammation, which is followed by serious adhesions, rendering subsequent operations difficult and hindering very much the expected radical cure. When operating for hernia in truss-worn patients one often finds the bladder adherent to the sac, and many an acute accident has happened in such cases where the bladder was seriously damaged by carelessly stripping it away from the sac. Various parts of the gut are often so adherent to one another, and sometimes to the sac, that one finds difficulty in separating them, and reducing such adherent structures in mass leads to serious postoperative complications. We also very often find, in large hernias, an irritated and even an inflamed appendix in the sac; which nee-sitates removal, and thus adds to the gravity of the case so far as prognosis is concerned. The exceptional cases, such as tube or ovary in the sac, no doubt you have heard of, and they also bother the operator seriously, to say nothing of the really dangerous cases, such as strangulated, gangrenous, or inflamed gut, with its complications, which are well known to you and need not be further discussed.

From the foregoing pathological considerations one might imagine the mortality of hernias to be very great, and the prognosis grave. Yet, looking up various statistics, I could not find one author who gave the mortality rate higher than two per cent. Does it pay, however, to lose even two patients out of one hundred cases? No. I say, emphatically no. A herniotomy in the early stage of the condition is an extraperitoneal operation, and your patient runs hardly any risk under ordinary aseptic precautions. It seems to me that a great many people have an enormous dislike to trust themselves in an unconscious state to others, and that may mean the anesthetist, or even the surgeon himself, and the nurses. Some dread greatly the aftereffects of the anesthesia, with its possible complications. Such people can easily be operated upon under a local anesthetic, such as cocaine, novocaine, beta eucaine, etc., in various strengths, according to the preference of the operator. Lately, injections of sterile water have been used very successfully, and the most recent local anesthetic employed is the solution of quinine and urea hydrochloride, from 0.25 to one per cent. A general anesthesia, however, is always the best if there are no contraindications, as in diseases of the heart or kidney, to its use.

Contraindications. There is no such thing as contraindication to operating in class a, as given above. Contraindications to operating in class b are those general diseases that menace life and health, such as general tuberculosis in an active state, diabetes mellitus, grave heart diseases, malignant growths, pregnancy in the late stages, blood diseases, such as pernicious anemia, hemophilia, Hodgkin's disease, splenic anemia, Graves's disease, etc. Age and sex are no contraindications, except in the very young (under one year of age).

Although I have condemned the truss and endeavored to show clearly the uselessness of its application, you are liable to lose many a patient if you insist on operation. I would therefore recommend the following rules for a well fitting truss (which is naturally very hard to obtain):

1. The head or pad should be of soft and yielding material.
2. The head should seal the entire opening and part of the marginal ring around it, so as to effectively prevent the viscus from coming out.
3. The steel rim, as well as the head, should not press too hard on the tissues; otherwise the skin and musculature will become numb and functionless.
4. The entire framework, and especially the head, must be immovable; this can be secured by means of straps arranged like suspenders worn over the perineum.
5. If it is an inguinal hernia the head should be of triangular shape so as to fit the groin.

After the truss is applied, in order to be certain that the hernia passage is secure, make the following trial. Let the patient cough, bend forward and backward, stoop down, with legs widely separated, and finally sit down with crossed limbs. If it is then secure, you may rest in comfort and consider that you have done something at least for your patient.

All these rules are hardly possible of application in a young and active individual, yet some patients want a truss, and if you do not accede to his wishes some kind colleague, the trussmaker, or even some enterprising druggist will satisfy his wants.

In conclusion, I will say that if only a few of you will follow in advising early operations, thereby preventing future complications during a delayed operation and also rendering life more pleasant for the patient, I will be amply compensated for bringing the subject before you.

218 East Fifteenth Street.

Therapeutic Notes.

Treatment of Constipation.—Léon Meunier, in Presse médicale for April 26, 1913, states that he has been struck with the fact that when, after a small enema of oil has been retained overnight, the rectum is washed the next morning with a solution of soda, the fluid evacuated contains sodium soaps. This is readily proved by filtering the fluid and
saturating it with sodium chloride, when a precipitate of soap is produced. Evidently the oil is in part broken up during the night into fatty acids and glycerin by digestive ferments still active in the lower bowel, and upon contact with the alkaline solution the fatty acid combines with it to form oleate of sodium. The latter being in intimate contact with the entire mucous membrane, cleanses it—in particular removing fatty substances—in a most effectual manner. Meanwhile, the oil itself has exerted the desired lubricant action in the overloaded gut.

Where these two indications are to be simultaneously met, therefore, the author advises that the patient be given in the evening an enema of two to four tablespoonsfuls of tepid oil, preferably oil of sweet almonds. This is retained overnight, and next morning the bowel is irrigated with 1 pint (1½ litre) of a hot (104° F.) solution of sodium carbonate or bicarbonate.

TREATMENT OF PRURITUS VULVAE. —A. Stein, in the Urologic and Cutaneous Review, January, 1913, in discussing the local treatment lays stress on the fact that neither water nor alcohol should be used in the preparations prescribed. He would even forbid patients to bathe, wash, or douche the affected parts until after the condition has improved. Instead of water he advises the application of olive oil, to be carefully repeated after each act of urination or defecation. This should be followed by the use of an ointment:

R

Cocaine, .............................. 20 grains (0.4 gr.)

Menthol, .............................. 20 grains (0.4 gr.)

Acidi salicylici, .............................. 20 grains (0.4 gr.)

Adipsis lanie hydrosi, ...................... 10 grains (0.2 gr.)

M. ft. ointment.

This should be applied in a thick layer on gauze, which is to be held in position by a T binder. To relieve itching, the placing of an icebag in contact with the parts, to remain over night, is also often effectual.

If causes such as diabetes, icterus, circulatory disease and parasites can be excluded, and if there is fluid and hypertrophy of the cervix, curettage and if necessary amputation of the cervix should precede the use of the local measures already referred to.

It is of great importance, also, to see that the patients have sufficient sleep and to relieve their extreme nervous excitability. Hypnotics may be used for the night, while during the day the following bromide mixture may be given:

R

Potassii bromidi, .............................. 30 grains (0.5 gr.)

Sodii bromidi, .............................. 10 grains (0.2 gr.)

Ammonii bromidi, .............................. 10 grains (0.2 gr.)

Aquæ destillati, q. s. ad. ...................... 1 fluid drachm (30 grains)

M. Sig.: One tablespoonful three times a day.

A SIMPLE METHOD OF ARRESTING EPISTAXIS. —Pech, in Bulletin médical. December 29, 1912, advises the following procedure: In the standing position and with the head erect, the patient makes constant pressure with the finger on the ala nasii of the side opposite to that on which the epistaxis is taking place and with the mouth closed, executes slow inspiratory movements, each lasting from five to eight seconds. Between inspirations the mouth is opened and expiration quickly effected. Two or three such inspirations are generally sufficient to arrest the epistaxis. This occurs owing to the relative difficulty in finding the entrance of air through the single nostril left open, the orifice being reduced to a mere slit owing to displacement of the septal tissues toward the ala of the side opposite from that compressed. A relative vacuum is thus produced in the thorax, as a result of which the blood pressure is lowered in the vessels of the head, this favoring clot formation at the bleeding point. That the mechanical effect thus exerted is a considerable one is shown by the fact that if the obstructed inspirations be continued much longer than is actually necessary, equilibration is impaired owing to ischemia of the brain.

TREATMENT OF INSOMNIA IN CHILDREN.—Comby, in Journal de médecine de Paris for April 26, 1913, urges in particular that the meals be given regularly, that coffee be interdicted, that the child be kept quiet before bedtime, and that the nervous system be toned up by life in the open air and cold affusions or wet packs. Constipation should be overcome with glycerin enemas or suppositories. Where there is much excitement, calmatives and hypnotics may have to be used. Thus the following solution may be given at bedtime to a child four or five years old:

R

Potassium bromide, .............................. 4 grains (0.25 gr.)

Chloral hydrate, .............................. 2 grains (0.125 gr.)

Syrup of aurantii flororum, ...................... 1 fluid dram (5 grains)

M. ft. syrup.

Or, a teaspoonful of the following may be given at hourly intervals until the desired effect is produced:

R

Potassium bromide, .............................. 4 grains (0.25 gr.)

Chloral hydrate, .............................. 2 grains (0.125 gr.)

Extract of hyoscyamus, .............................. 1 grain (0.0625 gr.)

Syrup of aurantii flororum, ...................... 1 fluid dram (5 grains)

M. ft. syrup.

An enema might be given as follows:

R

Potassium bromide, .............................. 4 grains (0.25 gr.)

Chloral hydrate, .............................. 2 grains (0.125 gr.)

Vinetae olei, .............................. 1 fluid dram (5 grains)

Syrup of aurantii flororum, ...................... 1 fluid dram (5 grains)

M. ft. syrup.

A solution of 7½ grains (0.5 gr.) of atropine in 2 ounces (60 grains) of water may also be administered in this way.

The following suppositories may be used:

R

Chloral hydrate, .............................. 2 grains (0.125 gr.)

Oleum theobromatis, .............................. 1 grain (0.0625 gr.)

M. ft. suppositorium unum.

R

Sulphonethylmethani, .............................. 3 grains (0.1875 gr.)

Oleum theobromatis, .............................. 1 grain (0.0625 gr.)

M. ft. suppositorium unum.

In malarial districts quinine should be tried, while in syphilitic children the best treatment for insomnia will consist in mercurial injections and potassium iodide.

TREATMENT OF GASTROINTESTINAL ATONY.—G. See, in Paris médical for April 12, 1913, is credited with the following combination for the purpose referred to:

R

Magnesii oxides, .............................. 3 grains (0.1875 gr.)

Creta pummaria, .............................. 2 grains (0.125 gr.)

Calamin palustris, .............................. 1 grain (0.0625 gr.)

Vanilla olibani, .............................. 3 grains (0.1875 gr.)

M. Sig.: One half teaspoonful before each meal.
MENTAL DISEASES IN THEIR RELATIONS TO THE INTERNAL SECRECTIONS.

Judging from the viewpoint of the general practitioner, at least, psychiatry—to which might be added its sister branch, neurology—does not afford as great a degree of satisfaction, in so far as therapeutic results are concerned, as do other specialties. An academic explanation of the morbid process supposed to be present in a given case is usually vouchsafed, but the results are in most cases disappointing. Modern researches, however, seem to be furnishing a clue to the cause of this unfortunate state of affairs. Defective anabolism through deficient oxidation and, conversely, imperfect catabolism of toxic wastes, have been known to explain many morbid phenomena of the cerebrospinal system, but the underlying cause of these departures from normal metabolism had remained obscure until the marked influence of the ductless glands upon these processes had opened a new field of study.

The intimate relationship between the internal secretions and mental disorders have been emphasized particularly through the labors of Lloyd Andriezen, McLane Hamilton, Laignel-Lavastine, Möbius, Dercum, Frankl-Hochwart, and others.

In a recent paper (Journal of the American Medical Sciences, August, 1913) the last named writer clearly sets forth the many landmarks which illustrate this connection. The onset of puberty coincides often, as we know, with the development of dementia praecox and other precocious mental aberrations. Disorders of the thyroid gland are prolific in such, as illustrated by the psychic anomalies observed, not only in certain cases of exophthalmic goitre, but also in the milder types of hyperthyroidism, in which excitement and manic outbursts are not infrequent. The asthenic stage of the same disease shows the converse of those witnessed during the erotic period, viz., a tendency to hypochondria, drifting at times into typical melancholia. Similar depressive psychoses are witnessed in myxedema or in its formes frustes, hypothyroidism. The tetany following removal of the parathyroids was shown by Frankl-Hochwart, and others since, to be attended in some instances by psychic phenomena in which excitement predominates. Removal of the thymus in young animals has been found to enfeeble their intelligence—the idiotic thymopria of Basch and Klosevoigt. The pituitary body, aside from the psychoses observed in the course of acromegaly and dystrophia adiposogenitalis, is distinctly the source, when the seat of a tumor, of psychic disturbances. Whether these are due to pressure upon the neighboring basal structures or to perversions of the glandular functions, matters little; an etiological connection between the pituitary and mental disorders is nevertheless an established fact. The adrenals seem also to merit attention, destruction of these organs having been found by Leri to coincide, in three instances, with melancholia. The pineal gland even has imposed itself upon the psychic field, a teratoma of this organ having caused in a five year old child so rapid a mental development that he reasoned as would a young man, with a predilection for ethical and philosophical questions—a point, perhaps, in favor of Descartes's view that the pineal gland is the seat of the soul!

Frankl-Hochwart closes with the remarks that "brain anatomy helps but slightly in showing how higher mental development is to be explained," and that "perhaps the time will come when we shall learn to perceive how much depends on the individual structure of certain glands and on their individual internal secretion." This will occur, in our opinion, only when the functions of each organ will be taken into account in the study of the morbid processes involved—and when the empirical use of organic products will have been replaced by their employment only where actually indicated and in appropriate doses.
PARINAUD'S CONJUNCTIVITIS.

Since Parinaud described in 1889 a peculiar disease of the conjunctiva associated with swellings of the lymphatic glands on the same side of the neck, a number of cases have been reported and its etiology has excited some discussion. Quite a number of writers have been insistent that the disease was a modified form of tuberculosis of a benign type in spite of the facts that it runs a self limited course, that the conjunctiva was not ulcerated, that inoculations of conjunctival tissue frequently failed to produce tuberculosis, that the tubercle bacilli were not usually found in the glands, that the proportionate number of patients in whom the tuberculin reaction was positive did not seem to be abnormally great, and that the histological examination of the tissue always appeared to indicate an infective origin. Those who did not accept this theory were obliged to content themselves with pointing out the objections to it, and with the hope that some day the morbid agent would be discovered. Dr. F. H. Verhoef presents in the Archives of Ophthalmology, for July, the reasons which lead him to believe that he had discovered this agent. Incidentally he holds that certain atypical cases of conjunctival tuberculosis may be mistaken for Parinaud's conjunctivitis, and have been reported as such, but that they do not possess its characteristic histological features. The characteristic feature is the occurrence of focal areas, varying in size and shape, infiltrated with endothelial phagocytes in various stages of necrosis, not packed close together and united with each other, as in tuberculosis, but discrete. The necrosis involves the cells alone and bears no resemblance to the caseation of tuberculosis. Surrounding these areas the tissue is densely infiltrated with plasma cells. Ordinary granulation tissue also is formed, the amount depending on the duration of the process. In eleven of his twelve patients he found in these areas of cell necrosis minute, filamentous microorganisms, for the most part in masses and intertwined about one another, though separate individuals also could be seen, by means of a technic that he describes in full detail. In one case, evidently an early one, numerous masses were to be seen in the superficial lymph spaces, and were especially prominent just beneath the epithelium, where the areas of cell necrosis usually occur. Such masses appear to be the starting points for areas of cell necrosis, for all the stages in the formation of the latter could be made out, beginning with the invasion of a mass of microorganisms by a few endothelial cells, and this one case alone seems to him to be sufficient to exclude the possibility that these microorganisms are secondary invaders. Their predilection for the lymph spaces explains the early involvement of the regional glands. Since no branching of the filaments could be detected he classes the microorganism as a leptothrix, and, so far as he knows, no similar one pathogenic for man has previously been described. The unusual character of these organisms, their great abundance, the fact that they were situated so as to explain the lesions, and the absence of any others that were demonstrable, lead him to believe them to be the causative agents of this peculiar disease. This can be made certain only by successful cultivation on artificial media, and the experimental production of the disease, preferably in monkeys.

ACTIVE IMMUNIZATION AGAINST DIPHTHERIA.

There is no phase of immunity of greater practical importance than the active immunization against infectious diseases. Important as the curative sera are, they nevertheless constitute merely a therapeutic agent. Valuable, it is true, but one which falls short of the ideal of imitating Nature in her lasting protection of races and individuals against infectious diseases. After all, prophylaxis is the ideal toward which we are striving, and any measure which brings us nearer to the goal constitutes an important advance along the line of battle that is being waged against the pathogenic bacteria. It is for this reason that Jenner's vaccination against smallpox has remained the classical example of active immunization. It showed the way. Pasteur's labors along the line of active immunization also furnished a clue, while the recent researches of Wright opened up a vista of great possibilities in the prevention as well as the cure of infections.

In a recent contribution to the Rousski Vratch (May 4, 1913) S. K. Dzerzhkovsky relates an interesting instance of a horse preserving its immunity against diphtheria for sixteen years, or almost its natural life. This horse served for the production of antitoxine and was sold. Sixteen years later it was repurchased and injected intravenously with 12,500 minimum fatal doses to guineapigs, this being the maximum amount of diphtheria toxine the horse received during the last immunization. No reaction followed. A second subcutaneous injection of the same quantity was followed by a slight general and local reaction. The horse was then bled, and the serum was found to contain 300 units of antitoxine to each cubic centimetre or about four times the strength this horse yielded during the first immunization sixteen years before. A similar result was obtained with a dog which was immunized against diphtheria for a period of thir-
teen months, yielding a serum of 3.5 units to each centimetre. A year later the dog, still showing an antitoxic serum of 0.897 units, was injected with toxine and yielded a serum of 30 units or nine times as strong. The author also experimented on himself, and seven years after active immunization with diphtheria toxine responded to immunization by inhalation with a serum five times stronger than the first. These observations show, according to the author, that active immunization produces such profound changes in the organism that the response to subsequent intoxication is very much greater, and this property to react may last for years. The comparatively brief immunity following a natural attack of diphtheria the author explains on the ground that the immunization period is too short. Another interesting fact brought out is that for purposes of immunization the doses of toxine need not be at all large. In fact, a dose too small to cause the slightest reaction may be sufficient to induce a permanent immunity. This is shown by the occurrence of natural immunity with previous apparent infection, as well as by the observation that healthy individuals often show antitoxine in the blood, such individuals having acquired the immunity by frequent exposures to minimal doses of toxine. It is quite probable that the comparative immunity of physicians and nurses to infection is due to their repeated absorption of small doses of toxine.

If the foregoing observations are correctly interpreted, may we not look forward to a time when active immunization will be accomplished by the introduction of small amounts of toxines, a procedure which would be perfectly harmless to the individual and yet effective in the production of lasting immunity?

THE MORTALITY FROM CONGENITAL DISEASES.

Until recently the principal cause of death among infants under one year old in this city was diarrheal disease. Thus, in 1908 we find that the deaths of such infants from diarrheal affections numbered 5,118, as against 4,533 from congenital diseases, and before that the preponderance of diarrheal deaths was even greater. Now, however, with the marked reduction in infant mortality during the past three years, a reduction confined almost entirely to diarrheal diseases, the congenital diseases have taken the first rank as a cause of death. These for the most part occur during the first month of life, and they produce no less than thirty-five per cent. of the total mortality under one year. Even so short a time ago as 1908 it was not considered possible to do much to reduce the number of this class of deaths. This view is taken in the annual report of the Bureau of Records of the Health Department for that year, where we read:

It will be seen that the most important factor in the mortality of infants is that of death from diarrheal diseases. The death rate from this cause is one that we may improve, and the many agencies working toward this end give promise of betterment in the future. The deaths from congenital diseases consist mainly of malformations and prematurity of birth, and are not, to any great extent, susceptible to official interference.

But at the present time these congenital diseases are attracting special attention, and it is believed that by prenatal care, particularly, much can be done to bring about conditions which will result in a material reduction in the mortality from this cause. At the conference on infant welfare held at Albany in June, the report of which has just been issued by the State Department of Health, this subject was taken up by several of the speakers, among them Doctor Pisek, of the New York Milk Committee. Dr. Florence Laighton, of the Russell Sage Foundation, expressed the opinion that there had scarcely been an undertaking for the prevention of infant mortality that showed evidence of greater promise than instruction given to the coming mother, and spoke of the prime importance of well organized cooperation on the part of those working in this field. Dr. Josephine Baker, chief of the division of child hygiene, Department of Health of the City of New York, was in accord with these views, and said that in the future the work for the reduction of infant mortality must be more and more educational and more and more social in character. The difficulties encountered in dealing with the congenital diseases are great, but the success achieved in the intestinal troubles of infancy affords some assurance at least that with systematic efforts concentrated in this direction the problem may eventually be solved.

VERTIGO IN GLAUCOMA.

In most of the cases of vertigo that come under the ophthalmologist's observation, this symptom is due to paralysis of the ocular muscles or to faulty refraction. Considered characteristic of ocular vertigo is the fact that it disappears upon closure of the eyes. L. Dor (Lyon médical, July 6, 1913) has recently directed attention to a form of ocular vertigo occurring independently of vision, i.e., arising even in a blind eye, and due to the intraocular tension of glaucoma. The dizziness at times appears suddenly, without direct relationship to an effort of visual attention, may be marked enough almost to cause the patient to fall, and can be overcome as a result of the emotion induced.
the patient becoming aware of a sudden influx of blood to the head, followed by relief from the vertigo. Dor asserts that at least one out of every four glaucoma patients suffers from this symptom, though special questioning may be necessary to elicit the fact, the patients often failing to associate the symptom with their diminished vision. Though other forms of vertigo, e.g., those of gastric, arteriosclerotic, and even of labyrinthine origin, may occur in these cases, the specific nature of “glaucomatous vertigo” is shown by its prompt relief through iridectomy, sclerectomy, enucleation, or even through the mere instillation of pilocarpine. Of four patients referred to by the author, three presented complete monocular blindness, and the fourth such restriction of the visual field as to amount practically to the same condition. The lesson drawn by Dor from these cases, then, is that even in the presence of a painless and visually incurable glaucoma, operative intervention may at times be indicated to overcome dizziness, the latter being very distressing to these patients and keeping them from enjoying to the full the visual capacity remaining in the other eye.

**New York and New England Association of Railway Surgeons.**—The twenty-third annual meeting of this association will be held at the Hotel Astor, New York, on Wednesday, October 22d. An interesting programme has been arranged, a prominent feature being the Address in *Commemoration of the Life of Dr. H. H. Young, of Baltimore.* The association, consisting of Railway surgeons, attorneys, and officials, and all members of the medical profession are cordially invited to attend. Dr. John W. LeSueur, of Batavia, N. Y., is president, and Dr. George W. Chaffee, of Brooklyn, corresponding secretary.

**Memorial Hospital.**—Postponing the opening ceremonies until the return of Dr. Winford Smith, medical superintendent of Johns Hopkins Hospital, and some members of the Marburg family, the hospital authorities have thrown the memorial services of Memorial Hospital open to patients. There are now twenty-three patients in the ward. The opening of the new ward relieves the crowded condition that has existed for some time at the hospital, several times during the past six months every ward of the institution being filled.

**Inspector, State Board of Charities.**—On September 13, 1913, the New York State Civil Service Commission will hold an examination for the purpose of obtaining a list of eligible persons to fill the position of inspector, State Board of Charities. The salary attached to this position is $1,200 to $1,500 a year. It is open to both men and women. Preference will be given to those of good general education, and to applicants between the ages of twenty-five and thirty-five. Those who have had twenty-five years' experience as clerks, or the like, will be similarly favored. One of the qualifications for the examination are: The State constitution, the State Charities Law, the Poor Law, and public and private charitable institutions in New York State, the history of the charity, and the problems of dependency, delinquency, and eugenics, and the discussion of some special social problem, to be indicated by the examiner.

**International Eugenics Congress.**—The International Committee, which met in Paris recently to decide upon the place and time of the next meeting of the International Eugenics Congress, succeeded in deciding to hold the next congress in New York in 1915, or about September 20th. The question whether only general meetings or sectional meetings also should be held was discussed, and a decision to this effect was arrived at. The subject of next year's congress will be Eugenics in the practice of medicine. Intending competitors must execute application blanks and file them in the office of the commission on or before September 5, 1913.

**American Electrotherapeutic Association.**—The twenty-third annual meeting of this association will be held in the Engineering Societies' Building, New York, on Tuesday, Wednesday, and Thursday, September 24th, 2d, and 4th. An interesting programme has been arranged, and the medical profession is cordially invited to attend. The members of the Association are: Dr. Edward Humphries, of London, England; vice-presidents, Dr. George F. Pfahler, of Philadelphia, and Dr. Edward C. Titus, of New York; treasurer, Dr. Emil Heuel, of New York; secretary, Dr. W. H. McPherson, of New York; registrar, Dr. Frederick M. Law, of New York; board of trustees, Dr. Charles Rea Dickson, of Toronto, and Dr. Thomas D. Crothers, of Hartford, Conn., one year; Dr. Francis B. Bishop, of Washington, D. C., and Dr. Frederick de Kraft, of New York, two years; and Dr. Fred H. Morse, of Boston, and Dr. William D. McPhee, of Haverhill, Mass., three years.

**Pellagra in Tennessee.**—The State Board of Health of Tennessee reports that during the month of June, 1913, there were reported 105 cases of pellagra throughout the State.

**Ohio State Medical Association.**—The sixty-eighth annual meeting of this association will be held in Cedar Point on September 24th, 25th, and 26th, under the presidency of Dr. J. M. Floyd, of Steubenville. Dr. J. H. Upham, of Columbus, is secretary of the association.

**Mr. J. Merton Taylor.**—Mr. J. Merton Taylor, president of the Taylor Instrument Companies, of Rochester, N. Y., died in the Rochester General Hospital, on Thursday, July 31st, at the age of sixty-seven years. Death was due to complications arising from an operation. Mr. Taylor was the son of the late George Taylor, founder of the Taylor Instrument Companies, manufacturers of thermometers, barometers, and other scientific instruments.

**Leprosy in St. Louis.**—Surgeon Carrington, of the United States Public Health Service, reported a case of leprosy in St. Louis, Mo., on August 6th, in the person of an ex-soldier, a native of Illinois, who had served in the Army at Cebu, P. I., in 1900, at which time there was a leper colony near the army post. The diagnosis of leprosy has been verified bacteriologically, and the patient removed to the municipal quarantine station.

**Gifts and Bequests to Hospitals.**—By the will of Joseph Kuder, who died in New York on July 24, 1913, the German and the St. Francis Hospitals will each receive $5,000.

The will of Henry Korn, a real estate dealer, who died in New York last October, contains bequests of $500 each to Lebanon Hospital, Mount Sinai Hospital, Beth Israel Hospital, and the Montefiore Home.

By the will of Mrs. Anna F. Franke, late of Philadelphia, the two sons of the testator are to have the income from an estate valued at $4,000, during their lives, and if they die without children two thirds of the estate will be given to the Pennsylvania Epileptic Hospital and the Colony Farm in Chester county, and the other third to the University Hospital.

The will of Henry Freedman, who died recently in Philadelphia, contained a bequest of $500 to the Jewish Hospital.
First Convocation of the American College of Surgeons.—The degree of the newly constituted American College of Surgeons, whose first convocation will be held in Chicago on November 13th, are to be conferred by Sir Rickman John Godlee, of London, who has accepted an invitation tendered to him by a delegation of distinguished American surgeons, the organizers of the College. The American Association of Surgeons, to which the convocation has been invited, have also been tendered a similar invitation to attend at its first meeting on November 14th. There will be 1,400 prominent surgeons of the United States and Canada.

American Public Health Association.—The forty-first annual meeting of this association will be held in Colorado Springs, Colo., from September 9th to 15th, under the presidency of Rudolph Hering, D.Sc., of New York. The work of the association has been divided into the following sections: Laboratory Section, Professor F. F. Gorham, of Providence; R. L. Lipman, chairman; and Dr. D. L. Harris, of St. Louis; secretary; Section in Vital Statistics, Dr. W. S. Rankin, of Raleigh, N. C.; chairman, and Mr. David S. South, of Trenton, N. J.; secretary; Section of Public Health Officials, Dr. P. M. Hall, of Minneapolis, chairman; and Dr. Richmond, W. W., secretary; Section of Sanitary Engineering, Colonel L. L. Ludow, of Winston-Salem, chairman, and Dr. H. D. Pease, of New York; secretary; Sociological Section, Mr. Homer Foster, New York; and Mr. S. L. Chittick, of Denver, secretary. An elaborate programme has been prepared, not only for the section meetings, but also for the general sessions, an interesting feature being a symposium on the control and improvement of food supplies. The association has also arranged a programme of entertainments for the visitors and their friends, which includes a number of excursions into the beautiful country surrounding Colorado Springs. The officers of the association are: Dr. Rudolph Hering, D.Sc., of New York; first vice-president, Dr. W. R. Batt, of Harrisburg, Pa.; second vice-president, Dr. James Roberts, of Hamilton, Canada; third vice-president, Dr. J. E. Monjaras, of Mexico; secretary, Professor Selskar M. Gunn, of Boston; treasurer, Dr. Livingston Farrand, of New York. The official headquarters will be in the Chamber of Commerce Building, and hotel headquarters at the Andlers Hotel.

International Congress on School Hygiene.—The fourth International Congress on School Hygiene will be held in Buffalo, N. Y., on August 24th to 29th. The officers will occupy a prominent position on the programme of the congress and some fifty of these public officials will discuss various phases of the work from the viewpoint of hygiene and sanitary inspection. Topics for discussion will include the organization of health departments in schools; the relationship of the school to the board of health; the equipment, training, and compensation of school physicians; school nurses; school clinics; relation of health supervision in the schools to the physician, the dentist, and the hospital; the relation of medical and hygienic supervision in the schools to health supervision in the home; sanitary supervision of school rooms, locker rooms, swimming pools, school books, and school furniture; supervision of disease carriers; prevention of epidemics; follow up methods and results; medical inspection and treatment. Among the two hundred and fifty contributors to the programme are college presidents and medical schools, county health officers, county board of education; teachers of public schools; professors of medical colleges; State, county, and city health officers; physicians in private practice; engineers, and architects. Moving pictures will be employed in many instances to illustrate the subjects under discussion. The delegates were given a tour of instruction for teachers in universities, colleges, and normal schools and the preparation of suitable books upon this topic for school use are scheduled for consideration. The Health Department of the City of New York will be represented by an exhibit on school inspection, and the following officers of its Division of Child Hygiene will attend the congress: Dr. S. Josephine Baker, director, Dr. John J. Cronin, assistant director, and Dr. A. H. Selskar, chief of the division. The secretary of the congress is Dr. Thomas A. Storrs, with offices at the College of the City of New York.

Pith of Progresso Literature.

Salvarsan Poisoning and Arsenic Susceptibility.—K. Brandenberg presents a typical clinical picture of death by salvarsan as follows: During the first days after the injection the symptoms are not so pronounced. Headache, elevation of temperature, gastrointestinal disturbance, moderate, slightly nervous irritation, paralytic developments, as double vision, an arrhythmic heart; later, restless, changed manner, slight visionary difficulties. On the third or fourth day a state of sudden collapse supervenes: deep coma, very severe epileptiform cramps, and a peculiar edema about the eyes and lips. It is mostly the young and healthy that are attacked. The autopsy in a sudden death from this remedy gives scant satisfaction. The brain shows edema and hyperemia, with or without capillary bleeding, fresh parenchymatous inflammation of internal organs, as of liver and kidney, at times hemorrhages of the intestinal mucous membrane. According to the author's opinion this is none other than a picture of arsenical poisoning. These results show, emphatically, a general or local idiosyncrasy to arsenical poisoning.

Comparative Examination of Influence on Body Temperature of Water, Carbonic Acid, or Mud Baths.—R. Schminke states that for practical purposes the mud baths, on account of their mild action on temperature, are to be preferred. Carbonic acid baths at 86° F. are more suitable for reducing body heat than water baths of the same temperature, because the specific heat of the carbonic acid bath is less than that of the water bath.

Treatment of Retroflexed Uterus.—B. Franqueau emphasizes the importance of treatment for the retroflexed uterus only when urgent indications demand it; indications for treatment are not the rule but rather the exception.

Acute Infections during Infancy.—E. Müller reviews among these: 1. The complex infection modernly designated as whooping cough; 2. diphtheria; 3. whooping cough; 4. varicella; 5. measles; 6. skin infections. Scarlet fever has no significance for this age; the nursing period is immune. Even mothers stricken with scarlet fever are permitted to give their nurslings their breast milk. The author considers whooping cough, the most harmful of these maladies. Under this he classes: 1. Catarrhal fever, especially of the respiratory tract; 2. enteric disturbances; 3. the forms of severe intermittent fever. Lesage's ingenious device against contagion is described as follows: Nurslings are isolated, separately, in what is called boxes, the walls of which are of transparent glass not reaching to the ceiling of the room, so as to afford free communication of air above the boxes. Thus the disease germs are kept within the boxes; they sink to the floor and perish. For fifteen years Lesage has successfully followed this plan of isolating the various infantile infections, except whooping cough, germs of which were known to float above the box walls. The author names four important condi-
tions affecting prognosis: 1. The constitution of
the infant. 2. The method of nourishment before
and during infection. 3. Environment. 4. The
character and severity of the existing epidemic.

Respiration a Mechanical Aid to Circulation.—
1. Hobbaner describes the mechanical influence of
respiration on the systemic circulation. The
muscles of respiration act as a motor for the circu-
latory apparatus and it is in this respect more ef-
fectual than the heart itself. The intestines and
large glands of the abdomen are relieved of venous
genengmement by the contractility of the muscles
brought about by respiration. Not only is the
venous blood of the liver aided in its passage back
to the heart by the respiratory act of the muscles
of the diaphragm, but the blood is also, by the same
means, propelled through the vena cava. The ab-
dominal muscles are the most effectual auxiliary
to the left heart. These last aid the return flow
from the lower extremities; peripheral engorge-
ment is relieved in the weakest part of the circula-
tion and edema of the lower extremities is effec-
tually prevented.

July 13, 1913.

Arteriosclerosis Occurring before the Age of
Thirty.—M. Hirsch discusses the generally er-
roneous belief that arteriosclerosis occurs only at
an advanced aged. Spastic conditions in childhood
are not so rare but what one may also find a spas-
tic state of the bloodvessels. The author empha-
sizes the importance of detecting the disease early
when the prognosis is favorable; the word, arterio-
sclerosis, will then no longer sound as a death
warning to patients.

Perrheunal.—S. Zawacki says that as an in-
nuce, trichlorbutyl ester of salicylic acid and
the acetylsalicylic acid, when used thrice daily,
lies never, so far as his observations go, caused
the slightest irritation of the skin. In muscular rheu-
matism perrenhal was used as a lubricant in mas-
sage, and its use was followed by a prompt relief
of pain. Most favorable results were observed on
all patients where the salve was used in pains of
joints both rheumatic and gouty.

Hematogenous Icterus.—J. W. McNeely concludes
from his investigations and observations that blood
pigments may be changed to biliary pigments with-
out the aid of the liver. He suspects that the endothelial cells of the vascular system, bone marrow,
and muscular apparatus, take part in this process.
Apparently, no exact histological examination
have been made. According to the author's re-
sarches, the endothelial cells rank first in consid-
eration as a cause of hematogenous icterus.

Indications of a Diet Free from Meat.—Pen-
quen reviews the diets proposed by various au-
torities, especially one by Klots, who recommends
the meat free diet for enureis nocturna. A vege-
table diet is given as an ideal for this malady.
In the absence of nitrogen, such preparations as plas-
mon, nutrose, sorbitone, etc., may be substituted.
The great decrease in the consumption of fluids
gives rise to no inconvenience. Coffee, beer, and
all alcoholic beverages are strictly forbidden. A
milk diet is not advised because of one thousand
parts of milk, six hundred pass out as urine. The
defluxion of milk is solely renal. Thirst may be
quenched by allowing fruits.

Physical, Chemical, and Biological Characteris-
tics of Thorium X.—Kahn explains the germicidal
power of thorium x by the examination of agar
plates which were at the same time protected from
the presence of air. With the growth of kress
seeds, it is seen that even small doses of thorium x
stimulate growth; by large doses growth is im-
peded; at the same time a difference in chlorophyll
content and root growth are observed. In all
plants treated by thorium x there is a branching of
the plant stem. In patients at the author's clinic it
was noticed that even small doses caused exanthem-
a and annoying sensations. Aside from leucem-
ia, no positive deductions can be drawn as to the
effects of this remedy.

July 20, 1913.

The Diagnostic Significance of Albumin Reac-
tion in Sputum.—H. Schmitz finds that: 1. In
most instances of insipid tuberculosis of the lungs,
even when expectoration is only slight, albumin
in varying quantities is found in the sput-
tum without the presence of tubercle bacilli; 2.
Without doubt, there are tuberculous pulmonary
diseases (fibrous forms) without the presence of
albumin in the sputum; 3. The albuminous content
of the sputum seems to depend upon the location of
the disease; generally only exudative inflam-
matory forms show a positive reaction. Generally
the proliferating form, which tends to cicatrization,
yields no albumin; 4. The quantity of albumin is
not an index in early differential diagnosis; but it
seems to stand in certain relation to the stage of
the disease and may perhaps be of value in form-
ing a prognosis; 5. In the albumin reaction of the
sputum we have an additional method of exami-
nation in tuberculosis.

The Action of Glanduitrin.—M. Mátýás used
glanduitrin in all stages of delivery. The results
were as good in the stage of dilatation with mem-
branes intact, as when they were ruptured early in
labor. The dangers of prolonged delivery could
be avoided by the use of glanduitrin. With most
patients it makes delivery prompt and easy. In
early rupture of the membranes and tardy pains,
the remedy should be used without delay. Through
its administration the necessity for the use of the
forceps is greatly diminished. In eclampsia glan-
duitrin produced no unfavorable results; it in-
creased the pains. In placenta praevia the author
has used it three times, aided by ballooning; rapid
dilatation was accomplished; after version and ex-
traction, living children were born. Glanduitrin
may therefore be considered a harmless remedy, in
suitable doses, for facilitating prompt delivery in
any stage of labor whether the membranes be rup-
tured or not. Disease of the heart, lungs, or kid-
neys is no contraindication.

July 27, 1913.

The Significance of Sweat Cure for Internal
Diseases.—A. Schwenckenbecher demonstrates
that in systematic treatment with hot water baths,
we possess a simple and easily procurable remedy,
which acts as a therapeutic agent in various dis-
ases. A valuable characteristic in this method of
PITH apt found the arteriosclerotic neoplasm. lack great because acidity, and tumor nization. Important, which associated he contracted he almost acid. He practised. Hot disease, viz., the excretion of increased quantities of nitrogen and of chlorides, and to diminish any possible edema.

**WIENER KLINISCHE WOCHENSCHRIFT.**

**June 26, 1913.**

**Early Diagnosis of Carcinoma of the Gastrointestinal Tract.**—Emil Schmetz points out that although the need of an early diagnosis of carcinoma of the gastrointestinal tract is most important, and though this is one of the localities in which the disease occurs most frequently, yet it is associated with great difficulty more often than when a cancer is found elsewhere. He makes some suggestions how early signs may be recognized. For the present we need to rely on clinical observations and examinations and to make a routine practice in every questionable case of gastrointestinal trouble of making functional tests, palpating the stomach, and investigating with the endoscope and the x rays. Beginning with the esophagus, this should be examined for stricture in every case of persistent vomiting or regurgitation soon after meals which is not readily explained by the presence of some known condition. He introduces first a stiff catheter, and if this meets with an obstruction, withdraws it and introduces a soft catheter, as he thinks more can be learned from the two than from either one alone. The x ray will clear up the diagnosis between an hourglass stomach and one that has been contracted by a cancer. Palpation is not always reliable, for this requires skill, and under certain circumstances the tumor cannot be felt, but nevertheless should always be practised. The first postulate for the recognition of pathological conditions in this manner is a knowledge of how the normal conditions feel, yet he has known experienced specialists to mistake a contracted loop of intestine, or the tense belly of the rectus abdominis for a neoplasm. When a tumor has been made out in the stomach the diagnosis of carcinoma is not positive, though such is its nature in the majority of cases. When the tumor is at the pylorus its presence can be recognized from the symptoms of stenosis more quickly than when it is elsewhere in the wall of that organ, because in the latter place it is apt to give no marked local trouble, and the accompanying general symptoms may be the first to attract attention. To differentiate between cancer and ulcer of the stomach the examination of the contents is of very great importance. Ulcer is accompanied as a rule by superacidity, sometimes with normal acidity and supersecretion, only exceptionally by subacidity, while in carcinoma free hydrochloric acid is almost regularly absent, subacidity is rare, and lactic acid is often present. He has never found lactic acid in a well marked case of ulcer, but he has repeatedly seen cases in which the history and course seemed to indicate ulcer with an absence of acidity or with subacidity and lactic acid, which proved on histological examination to be carcinoma. Inversely he has seen large tumors with superacidity which proved histologically to be ulcers. Hence he believes that the diagnosis of carcinoma should be made in every case of pyloric stenosis, whether a tumor can be felt or not, when free hydrochloric acid is absent, or lactic acid is present. He found achylia in scarcely three per cent. of 830 noncarcinomatous cases, a lack of hydrochloric acid in only seven per cent. of nearly 1,000 cases of noncarcinomatous diseases of the stomach, while hydrochloric acid was wanting in over seventy per cent. of 150 cases in which carcinoma was present. The diagnosis of cancer of the intestines is possible only through symptoms of stenosis, or the demonstration of a tumor, and, even then, the diagnosis is only probable. He suggests giving the patient a dose of a purgative mineral water, and palpating the intestines a few hours later. An accumulation of fluid may be found above the constricted portion. Symptoms of disease of the lower portion of the intestines, such as hemorrhage, mucus, or tenesmus, should lead the physician to make a rectal examination, although he thinks that this is not done in a great many cases, so that the disease is not recognized until late in its course. He sees many patients yearly who have been treated for chronic intestinal catarrh, at Carlsbad and elsewhere, without endoscopic examination, or even digital exploration. Such examinations are necessary in order to make an early diagnosis.

**Gangrene of the Extremities and Its Treatment.**—Hans Ehrlich and Marian Maresch report eighty-one cases of gangrene met with in von Eiselsberg's clinic between April, 1901, and the end of March, 1913. The gangrene was due to electricity in one case, to embolism in two, to freezing in two, to ligation of the popliteal artery in three, to arteriosclerosis in forty-four, to diabetes in twenty-nine. In the case caused by electricity a boy laid his hand on a live wire; amputation of the arm was necessary. The cases of embolism were due to puerperal sepsis. The popliteal artery was ligated in one case because of a wound, in two because of aneurysm. The cases of arteriosclerosis are of more interest. The patients had usually suffered for years from paresthesias, chilliness of the limb, rheumatic pains, or intermittent limping. The lower limbs were the ones almost always affected, the process usually beginning in the toes, more rarely in the skin of the back, or the sole of the foot, or of the leg. The anemia or cyanosis of the skin may last a long time, with considerable pain, before the patients die. Frequently the process has from the start an inflammatory character, beginning as a paronychia, or an ulcer of the ball of the great toe, and then suddenly the true state is revealed by an intense lymphangitis and a disturbance of the circulation with edema and cyanosis of the leg. In many cases the gangrene starts from a slight local trauma, such as the pressure of a shoe, or an operation for ingrowing toenail. The pain is very severe and has a bad influence on the general condition of the patient. Mummification is not characteristic of arteriosclerotic gangrene.
though it is more common than the moist variety. Prophylactic and conservative measures are indicated, hence it is important that the condition should be recognized early. Conservative treatment consists of rest in bed, the internal administration of potassium iodide, elevation of the limb, and the application of ointments when ulcers are present. In all forms of gangrene which are not caused by a diffuse or progressive disease of the arteries, as after wounds, burns, or freezing in young people, demarcation should be awaited and amputation performed in healthy tissue unless an earlier intervention is forced by sepsis. In cases of arteriosclerosis, when the condition otherwise is good, the spontaneous sloughing of the toes should be encouraged, as the slight prospects of a permanent cure discourage extractions in the foot. When amputation is necessary because of faulty demarcation, extension of the process, infection, or unbearable pain, in senile gangrene, it should be performed in the thigh. In presenile gangrene good results can be obtained by amputation of the leg if the extent of the process offers no contraindication, the popliteal pulse can be felt, and the stump bleeds freely during the operation. Any amputation performed on a diabetic must be of the thigh.

Pseudotuberculous Ulcers on the Female Genitals.—G. Scherber says that these ulcers are distinguished by their appearance, their rapid development, their acute inflammatory nature, and their painfulness. The disease comes on with or without high fever, with redness and swelling of the labia, and a subjective sensation of burning which is increased, by touching, to severe pain. At the same time numerous gray white or gray yellow nodules, as large as pinheads, appear, which enlarge somewhat and break down into apparently follicular ulcers. The inguinal glands may be swollen. These ulcers respond readily to mild antiseptic measures, but when mistaken for syphilitic sores and not treated locally they persist for a long time.

ZEITSCHRIFT FUR AUGENHEILKUNDE.
July, 1913.

Therapeutic Experiences with Lipojodin in Some Diseases of the Optic Nerve and Retina.—A. Dutoit finds lipojodin to be a very valuable remedy in the treatment of optic neuritis of infectious or toxic origin. The improvement of the vision is common quickly and appears to be constant, but the remedy must be used for a long time. The same is true to a certain extent of diseases of the retina. It seems to be of especial value in senile degeneration of the macula. The preparation is given best in the form of tablets, in doses of from 0.3 to 1.5 grammes. No unpleasant aftereffects have yet been noticed even with doses as large as 5 grammes a day.

LYON MÉDICAL.
July 20, 1913.

Effects of Salvarsan Enemas in Certain Forms of Tuberculosis.—P. Cournot and Durand, having found, with Nicolas, Charlet, and Gâté, that in certain syphilitic patients there developed an increase in the agglutinative power of their serum toward the tubercle bacillus after injections of salvarsan, undertook to administer small doses—0.1 grammes—of this drug by enema to nine tuberculous patients. Each patient was given eight such injections in the course of four weeks. The results varied greatly in different cases. It seemed as if patients with grave tuberculosis with extensive lesions and steady progression of the morbid process might be rendered worse by the salvarsan. Other patients, however, were improved by it, sometimes most strikingly so; these were the patients in whom the customary tuberculosis treatment had already given favorable results. Preliminary administration of sodium arsenate seemed to be useful both to accustomed the patient to arsenic and to indicate whether the more energetic salvarsan arsenical treatment should be instituted. The agglutinative power toward the tubercle bacillus was not increased by the salvarsan enema, where it had previously been nil or very slight; it was greatly increased, on the contrary, in cases where it had already been high, and this increase seemed to afford a good prognostic omen as regards the result of the treatment. Salvarsan enemas would seem to be useful as a reinforcing therapeutic measure in certain tuberculous cases, accelerating the improvement where such is already taking place. Their action should be controlled by keeping under observation the patient’s general condition, the weight curve, and the agglutinative power of the serum.

PRESSE MÉDICALE.
July 19, 1913.

Alcohol and Alcoholism from the Biochemical Standpoint.—Maurice Niclou finds it difficult to believe alcohol a normal product of carbohydrate metabolism since only extremely small amounts (0.018 c. c. in one liter of blood) have been found in the blood. Ingested alcohol enters all tissues and secretions. The milk, in particular, contains it, even where the amount taken has not been sufficient to cause “intoxication.” Experiments conducted by the author showed that alcohol passed freely into the secretions of the male reproductive organs as well as into the blood of the fetus from that of the mother. Such findings permit of readily accounting for what is clinically known as “alcoholic heredity,” which has for its consequences premature births, abortions, high infantile mortality, and later, physical and mental degeneration. There may with propriety be coined the term “congenital alcoholism,” to designate the effects of alcohol on the embryo, beginning at the moment of conception.

Primary Acute Orchitis in Children.—L. Ombréan refers to that form of acute orchitis formerly attributed to masturbation and at present described in textbooks generally as an acute inflammatory form of testicular tuberculosis. The condition is characterized by a rather sudden onset, pain of varying intensity, temperature of 37.5° to 38° C., edema and redness of one side of the scrotum, enlargement of the testicle, little or no fluid in the tunica vaginalis, and opacity of the
mass. The author operated in seven successive cases seen in the last two years and was surprised to find torsion of the spermatic cord in four instances, with the probability, moreover, that torsion had existed in one and perhaps even two of the remaining three patients. From this the author is led to divide the condition manifested in the symptons already referred to into two, viz., cases of true orchitis and cases of torsion. The former appear to be neither gonococcal nor related to a general infection, and a tuberculous origin also seems doubtful, inoculation of a guinea pig in the author's case proving negative, and the patient's operative wound healing by first intention. In the torsion cases, certain facts seemed to suggest masturbation as a cause. Three grades of local disorder were found at operation, viz., edema and turgescence of the epididymis with inversion of the testicle, testicular apoplexy, and abscess with necrosis of the gland. To differentiate torsion from orchitis without operation is difficult. On the whole, since if in a given case torsion exists, conservative treatment may be followed by destruction of the gland, intervention should be early practised in case of doubt. Where supravaginal torsion is found, the vaginalis should be fixed to the scrotum, and where intravaginal torsion exists, the testicle should be fixed to the vaginalis and the latter to the scrotum.

July 23, 1913.

Vaccine Treatment in Whooping Cough.—L. Lagane calls attention to results recently obtained by Nicolle and Conan by the administration in pertussis of living cultures of the Bordet-Congou organism. From one to five drops of an emulsion of this bacillus—about 1 to 5 million bacilli—washed and heated to 40° C. for half an hour, were given subcutaneously every two or three days to 70 children suffering from pertussis. In the series of cases, 35.7 per cent were cured, 36.46 per cent improved, and 25.66 per cent unimproved. Seventy-eight per cent of the cures were obtained after two to five injections, i.e., within three to twelve days. The greatest percentage of cures was not observed in the cases treated early, but in those in which the disease had already been present two to three weeks. Lagane considers these results "encouraging," and suggests that if the method were used for prophylactic purposes it might prove of even greater value.

Inequality of the Radial Pulses in Chronic Syphilitic Aortitis.—Laingel-Lavastine and Vin- hit report three cases illustrating this condition. Sphygmonanometeric examination showed in each a marked difference in the systolic pressures of the two arms, though the diastolic differed by only 10 or 20 mm. Hg. The sphygmonogram on the side with low systolic pressure showed weakening, retardation, and deformation of the pulse wave. In each instance radiography and orthodiography showed clearly that there was no aneurysm but merely elongation, slight dilatation, and a sinusous course of the aorta. This was confirmed at autopsy in one of the cases. The presence of syphilis was shown in at least one case by the marked improvement following mercurial treatment.

BRITISH MEDICAL JOURNAL

August 27, 1913.

General Toxic Effect of Heavy Metals after Subcutaneous Injection.—Benjamin Moore and his collaborators, G. F. Oldersham and O. T. Williams, have conducted comparative studies on the lethal doses, sites of action, and paths of elimination of several of the heavy metals, namely, copper, zinc, silver, tin, arsenic, and lead. The heavy metals, as a class, have a common and preponderant toxicological characteristic, namely, the production of marked irritation, congestion, and destruction of the intestinal mucosa, caused by local accumulation and excretion, via the intestine, of the heavy ions. These effects are almost identical with those caused by the saponins or sapogluco- sives. It is remarkable, also, that both these latter substances and the heavy metals are not absorbed from the gastrointestinal tract. A specific affinity seems to exist between the intestinal columnar cell and these chemical bodies. This relation is extremely selective, allowing the drugs to pass through the cells in the direction of excretion even at the expense of the cells, and absolutely resisting absorption from the intestine without damage to the same cells. Death from the heavy metals is due to shock and collapse, secondary to the destruction of the intestinal cells. Perhaps the most remarkable observation is that with these metals the lethal dose is not proportional to body weight, but is nearly proportional to the two thirds power of body weight—that is to surface, the surface being that of the intestine. For example, in the case of copper the white mouse is found to be 2.5 times as resistant as the guineapig. Such an observation throws light on the arsenic treatment of trypanosomiasis in the rat and in man. In such a case the rat would probably have five times the factor of safety of man, and it would be easy to reach a blood concentration in the former sufficient completely to sterilize the blood of parasites, whereas in man such a concentration is usually impossible on account of his greater relative intestinal surface area and consequent lower resistance to the toxic action of the heavy metal. It has been suggested that volatile lead compounds are given off in the drying of paint, or that other volatile substances are liberated which render men susceptible to the actions of lead. A series of careful intensive pharmacological experiments by the authors seem utterly to disprove the truth of these contentions. The most valuable deduction to be drawn from this report is the necessity for the promotion of excretion, via the intestine, in cases of chronic poisoning in man by the heavy metals.

The Influence of Copper upon the Growth of Mouse Carcinoma.—A. J. Gelaire's experiments, while not by any means conclusive, seem to show that copper tends to arrest the growth of mouse carcinoma in a large proportion of cases. In a much smaller proportion the tumors have undergone retrograde changes. He used cuprammonium sulphate by subcutaneous injection and colloidal copper in the same way and by intravenous injection. The latter drug and the intravenous channel seemed to give the best results.
LANCET.
August 2, 1913.

A Fatal Illness in Children Associated with Acute Interstitial Parotiditis.—All four of M. H. Gordon's cases obviously were of the same nature. Among the common features were: Drowsiness as an initial symptom, coma, and sunken eyes with dilated pupils; muscular rigidity in some form, stiffness of the neck muscles, retraction of the head, and Kernig's sign in most cases; Babinski's sign was present in two; all patients had some fever and a rapid pulse, together with some vomiting and diarrhea. The cerebrospinal fluid was under increased pressure, and showed a lymphocytosis in every case. A leucocytosis was present in every case, and a relative lymphocytosis was equally constant. All four cases presented similar post mortem lesions—namely, congestion of the meninges and central nervous system, slight and variable lymphocytic infiltration of the pia, some variable increase in the glial cells, and wasting and chronicolysis of some of the anterior horn cells. All cases showed more or less extensive foci of acute interstitial inflammation in the salivary glands, most marked in the parotid. No sign of tuberculosis could be discovered, and cultures of blood and cerebrospinal fluid were constantly negative. By a process of elimination Gordon comes to the conclusion that the condition was one of atypical mumps.

The Production of Ulcer of the Stomach in the Rat.—Charles Singer succeeded in a large majority of cases in inducing single or multiple gastric ulcers, by keeping his animals in unsanitary surroundings, and feeding them with food contaminated with their own fecal matter. Ulcers developed in an even larger proportion when the diet was contaminated with the fecal matter from rats suffering from ulcer. But even under the latter diet ulcers did not develop in rats when the animals were kept in sanitary conditions, so that they retained their full health. This suggests that ulcer is possibly due to an infection by an organism normally present in some other part of the digestive tract but which is unable to cause the lesion when the normal protective powers are preserved.

Arsenic Cancer.—In concluding their paper on thirty-one cases of arsenic cancer, R. J. Pye-Smith and his associates give the following summary: There is a remarkable similarity in many of the features of the series of cases. In nearly all cases arsenic had been taken for periods extending over years. In nearly all hyperkeratosis was present, especially in the palms and soles, and of a type often produced by arsenic. The cancerous lesions were multiple in fully half of the cases, a fact suggestive of the presence of some general and unusual predisposing or exciting cause. Some special cause is also suggested by the fact that in one fourth of the cases the age of the patients did not exceed thirty-five years. In several of the cases the use of arsenic had been discontinued many years before the cancerous changes developed, pointing to its being an early or remote rather than a late or final cause. The epitheliomatous process always began in the skin and in most of the cases it appears to have started in a patch of keratosis, probably never in normal skin, and seldom, if ever, in a patch of psoriasis. This shows that psoriasis, though present in two thirds of the cases, is probably not a causative factor. In nearly two thirds of the cases the lesions were on the upper extremity, usually the hand; on the lower extremity, especially the foot, in a fourth of the cases; the rest of the cases were nearly equally divided between the trunk and neck and the external genitals and perineum. In only one instance was the face affected. The great frequency of involvement of the hands and feet suggests that either trauma or the keratosis, so generally present there, was a determining factor in localization. Excision of the cancerous lesion or amputation was done in two thirds of the cases and in many instances local recurrence followed. Metastasis took place into the glands and internal organs in about a fourth of the cases. Three times as many men were affected as women. It seems reasonable to conclude that, while arsenic plays a definite part as an indirect etiological factor in the small group of cases known as arsenic cancer, there is no probability of its being of etiological importance in the great majority of cases of cutaneous epithelioma, and still less in cancer generally, in spite of the fact of its very wide distribution in nature. The prognosis in arsenic cancer is, apparently, at least as bad as it usually is in cases of epithelioma of the skin.

A New Guaiacol Chloride Compound.—John McMechan reports several cases in which he has used this new drug and, though the reports are not very convincing to the careful observer, he feels justified in offering the following conclusions: 1. That mixture of guaiacol chloride controls and relieves asthma and the dyspnea of emphysema in a rapid and satisfactory manner. 2. That it has the peculiar property of being eliminated as a powerful local antiseptic at the uterus, where it acts as a curative agent in chronic and acute septic conditions. 3. That it acts as a lung stimulant and antiseptic in many forms of chronic bronchitis. 4. That its value in the medical treatment of early and incipient phthisis, and also in some of the chronic forms, especially those in which the temperature is usually normal, requires further working out, and at the same time is of a promising character.

PRACTITIONER
July, 1913.

Clinical Notes on Phlebitis.—Dyce Duckworth considers phlebitis to be a disease for the care of physicians rather than surgeons. The treatment is both regimenial and medicinal. Posture is of the first importance, and rest of the involved part is essential. If a leg is the seat of the process it must be laid out horizontally, the knee slightly flexed, and the foot everted. A pillow under the knee, supporting and slightly raising the ankle, secures rest. One part of belladonna liniment to four of warm water should be applied on lint, well soaked, and loosely bandaged over the vein. This is to be covered with oiled silk and lightly bandaged. This is all that is required locally. An aperient of calomel, colocynth, and henbane, in pill, should be given over night, and a dose of any saline powder or water taken the following morning. It will be advisable to repeat this saline dose several mornings
in the week. Citrate of potassium or sodium, and citrate of lithia with compound tincture of bark in an ounce of sarsaparilla decoction, taken twice a day, is a useful medicine. The diet is very important. It must consist chiefly of fish, eggs, and light puddings. Well cooked green vegetables are advisable—fresh, tender lettuce, and cooked fruit, apples by preference. Strong coffee should be avoided, but weak tea or Vichy water are allowed, and a little whisky, if the circulation is feeble. Freely made lemonade may be taken. Milk is to be avoided because it is rich in lime and may tend to promote clotting. Whey is a safe liquid to employ. Extra drinking of water, distilled if possible, is very advisable. Milk is inadvisable in all cases of viscosity of the blood. Care must be taken at first on assuming the erect position, no sudden movements should be made. Bending the knee of one limb in getting into bed has proved fatal in several cases, by causing rupture of the clot and embolism of the pulmonary artery. The patient should sit on the bed and have the legs raised by an attendant. The affected limb should be bandaged carefully for some weeks. It may sometimes remain permanently enlarged and more clumsy than the sound one. At a later period warm douching and gentle massage may be employed. Massage should be avoided till the circulation is reestablished.

Cystic Mammary Tumors.—Harold Upcott says that as an exact diagnosis in these cases is possible only through an exploratory incision, this incision should be made deliberately through the overlying structures until the cyst wall is exposed; then the cyst may be opened, the nature of its contents observed, and finally explored. If the knife passes through an indurated, gritty area before opening the cavity, malignancy may be suspected; if the cyst contains bloody fluid, and there is no papilloma to account for it, or if the contents are thick and gumous, it is certainly cancer. A hard nodular excrescence on the cyst wall justifies a radical operation. Personally, he thinks the breast should be removed in any case, for the surgeon should act on the principle that every tumor of the breast of a woman over thirty is cancer until it is proved to be otherwise.

Inoperable Cancer and Radium.—A. A. Warden finds from his experience in these cases that radium relieved the pain, temporarily arrested the growth, temporarily destroyed the cancer cells, had no effect on metastasis, and probably prolonged life. He believes that radium has established a claim to be tried not only in hopeless cases, but in those in which gland infection and cachexia have not yet reduced the patient’s chance to a minimum.

On Arterial Spasm.—O. K. Williamson says that broadly speaking, for other than broad general statements are inadmissible, inasmuch as each case must be treated on its merits, treatment should in the first place be directed toward relaxing the vascular spasm. If the sphygmonanometer yields a low reading, it will be necessary to stimulate the heart and thus endeavor to minimize the danger of thrombosis. If, on the other hand, the reading is a high one the question to be decided is, how much of this is due to the resistance of the arterial wall, and how much to actual blood pressure. This decision can be made only by the use of the trained finger. If the conclusion is arrived at that the actual blood pressure is low, then a stimulating line of treatment should be adopted. If, however, it is high, such treatment must be avoided. We have, in fact, to steer between the dangers of thrombosis and of hemorrhage.

Cyclic Vomiting in Children.—Hugh T. Ashby says that on the theory that the liver is at fault, and that there is an absence or nonusage of the carbohydrates, we give sugar in large quantities during an attack, and, if possible, before an attack comes on. The best way to give it is as glucose in soda water, giving an ounce of glucose every two hours by mouth. The children get very thirsty during an attack and are only too eager for drinks; a good deal is vomited, but if a drink of glucose and soda water is given soon after an attack of vomiting some of it will be absorbed before the next attack comes on. The glucose should also be given by the rectum in large quantities, as this seems to materially shorten an attack and make it less severe. If the parents can tell when an attack is coming on, the glucose should be given at once to ward it off, or at least to shorten it. The bowels should be kept freely moving with enemas, and if the child during an attack is getting worn out by the continual vomiting and retching, a small injection of morphine often helps to diminish the vomiting and to give some rest. He thinks that this treatment is more rational and productive of better results than the use of bicarbonate of soda in large doses.

The Treatment of Infantile Diarrhea by Saline Injections.—H. B. Day maintains that saline injections alone, without drugs, are capable of curing most cases of infantile diarrhea. Quinton’s marine plasma has no definite superiority over artificial saline of the same strength. Such hypertonic solutions are preferable to weaker (0.75 per cent. or less). The administration of medicine is preferable to injections of saline as a routine treatment of infantile diarrhea. Disregard of dietary instructions is the commonest cause of failure of outpatient treatment. Injections are valuable in proportion as the loss of fluid by vomiting and diarrhea exceeds the intake. They should be given before actual symptoms of collapse arise. The disadvantages of saline injections as compared with medicinal treatment are thus summarized: 1. It entails a certain amount of preparation and the insertion of a needle, a procedure resented more by the mother than by the baby. 2. A course of daily injections is usually necessary to secure success. It may be difficult or impossible for the patients living at a distance to attend so often. 3. Much valuable time is taken up in giving the injections. On the other hand, saline injections have the following points in their favor: 1. The treatment is carried out under direct supervision, whereas the administration of drugs is chiefly entrusted to the mother. 2. Any treatment which necessitates daily observation of a case is more likely to succeed than one in which attendance may be irregular. 3. Saline injections are the recognized treatment for collapse. The early use of injections is of value in combating the exhaustion feared in bad cases of diarrhea and vomiting.
On “Tunnel” and “Caterpillar” Skin Grafting.—Alexander Macleman described a method of introducing skin grafts beneath granulations, which he called tunnel grafting and described again in detail. Now he presents another new method which he calls caterpillar grafting because the graft is made to crawl on to the ulcer. It consists in cutting a long strip of skin running up to, but not entering, the ulcer. The top end is pointed and detached. The flap is then doubled on itself and a single stitch retains it in its new position. The raw surface left behind is closed by a continuous suture. The flap should be broad, not less than one inch, and should not be longer than five inches. After the pointed end has acquired a firm hold in its new bed, the other end is cut into the ulcer and the caterpillar is strengthened out, the fold then being formed of the granulations and part of the bed of the ulcer. After the graft has acquired a hold, the elevated part of the ulcer, carrying the former blood supply of the caterpillar graft, is cut away; thus, a long sound strip of the entire skin is planted across or well into the ulcer. The flap should not be stitched to the cut edge of the granulation tissue in the ulcers, but the edges should be drawn together by mattress sutures passing below the graft, so as to avoid interference with the blood supply of the new strip of skin. This method of grafting the writer does not think of such general utility as the tunnel method, but it is suitable in some cases.

The Picric Acid and Camphor Treatment of Ringworm.—Agnes Savill uses a lotion consisting of picric acid, seven grains; camphor, one half ounce; and rectified spirit, one half ounce, with excellent success in the treatment of ringworm.

SOUTH AFRICAN MEDICAL RECORD.
June 14, 1915.

A Critical Review of Recent Experimental Leprosy Research.—This elaborate review is made by H. Bayon, who says, at the outset, that the paramount and most urgent question in connection with leprosy at the present moment is the outcome of a bacteriological problem. The importance of settling, once for all, whether the microorganism of leprosy can be artificially cultivated on nutrient media, or the disease transmitted to animals, can hardly be exaggerated. He first endeavors to settle the contradictory points in relation to the staining properties and the morphology of the microorganism, and then takes up successively the attempts by various investigators to cultivate this, the transmission of leprosy to animals by inoculation of the human “virus,” rat leprosy and its relation to the human disease, the serology of leprosy as a means of diagnosis of the disease and for the purpose of controlling specific treatment, and the communicability or contagiousness of leprosy. In regard to the last named he says that a careful review of the literature on the subject cannot but lead one to the conclusion that it is with relative ease communicable from the diseased to the healthy, under unhygienic conditions, by intimate personal contact. Where the principal rules of hygiene are observed, and contact is not intimate, the proportion of risk diminishes to a vanishing point; so that only one individual in a thousand, or even less, may become infected. In the discussion of the results of his critical review the author states that the consideration of Hansen’s bacillus as the end stage of an actinomyecotic germ, is the only view which explains the extreme difficulty encountered in gaining a pure acid fast culture, the frequent isolation of partially acid fast diphtheroids by numerous independent workers, the low pathogenicity of the virus for animals, and the extreme capriciousness with which leprosy is transmitted, even under favorable circumstances, such as would be the case between mother and child. It explains, up to a certain point, how people can live for years with lepers without contracting the disease, while in other instances a very short stay in a leprosy area has been sufficient to bring about infection. It is to be expected that a bacterium with such a complicated developmental cycle will have equally varied degrees of infectivity; which, again, can also be followed by an absolutely different complex clinical set of symptoms. No explanation of these obscure points has even been attempted, nor is light on the subject to be expected, until we are enabled to base our calculations on a large series of experiments. The results of this critical review of recent research on the bacteriology of leprosy, Bayon says, can be summed up in these few words: Those microorganisms, isolated from lepers, which not only present a morphological identity to the bacillus in tissues, but also produce lesions absolutely identical with those brought about by the injection of virus into receptive animals, have a first claim to be considered pure cultures of Hansen’s bacillus. He attempts to prove that this postulate has been fulfilled by Kedrowsky’s and Bayon’s strains of leprosy by a number of drawings, which give a comparative illustration of the lesions caused by various microorganisms, and which, he holds, bear out many of the statements made in the course of the paper. He does not wish, however, that any opinion of his should be taken for granted without a careful valuation of all the evidence available to elucidate the knotty points of a problem which has baffled research for over thirty years, but which now shows signs of yielding to the pertinacious efforts of some of the more insistent of numerous investigators.

BOSTON MEDICAL AND SURGICAL JOURNAL.
August 7, 1915.

The Surgeon and the Ptosis Problem.—F. B. Lund says that it is not an uncommon belief among surgeons that a careful review of the large number of cases reported by those who have operated freely in this field would show a large proportion of real failures from a therapeutic point of view. For this reason conservatism and candor in reporting results are to be desired, as well as optimism and courage in proceeding with this work.

The Rôle of Gastric and Intestinal Stasis in Some Cases of Epilepsy.—Hale Powers reports five cases of both grand and petit mal, the histories of which differ widely in most respects, the patients suffering more when constipated and when careless about diet, and having been benefited by diet, laxatives, and exercises. Two improved while not taking bromides. The x ray demonstrated stasis in
three, but not in two, in one of which there was an arrest of the disease and in the other only the lightest of petit mal attacks. The amount of stasis was in proportion to the severity of the disease. In one case there was atony of the stomach, with a question of iliac stasis. In another there was marked ptosis, the greater curvature of the stomach being below the iliac crests and the transverse colon down in the pelvis, with consequent lengthening and accentuation of the hepatic and splenic flexures. One patient had never taken bromides. In one there was a history of cerebral syphilis and of epilepsy developing five years after the primary lesion, but the epilepsy appeared at a time when the patient was debilitated from overwork and was drinking to excess, and the gastrointestinal disturbance so caused may have been the cause of the epilepsy. In one case there was consanguinity and epilepsy in two uncles, but it must be borne in mind that anomalies of the viscera, such as ptosis, are sometimes hereditary, and that epilepsy in this patient may have been the result of an inherited tendency toward entropion, rather than of inherited "instability of the nervous system."

**JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.**

_August 9, 1913._

**Our Tendency to Fads,** by Joseph Zeisler.—See this _JOURNAL_ for July 5, p. 42.

**Nephritis; Its Treatment with Thyroid as a Preliminary to Operation,** by J. F. Percy.—See this _JOURNAL_ for July 5, p. 38.

**Necessity of Consent to Operations,** W. S. Wermuth deals first with the matter of the consent of the patient himself and then of the consent of those other than himself, and expresses the opinion that the safest practice is to obtain the consent of the patient. If the patient is a wife, that is probably sufficient. If the patient is a child, at present the consent of the parent should be obtained. If the patient cannot consent, every effort should be made to gain the consent of some relative. Carefully explain the scope of the operation to the patient, or, if that is clearly inadvisable, to the nearest relative. Operate no more than outlined except in dire emergency.

**Three Cases of Amebic Dysentery Treated with Salvarsan,** S. H. Wadhams and E. C. Hill report these cases. Two were given neosalvarsan, and one, salvarsan, and all three patients recovered. The first was treated for syphilis, and it was not at first known to the authors that he suffered from chronic amebic dysentery; so that the discovery of the apparently curative effect of the neosalvarsan was accidental. It is perfectly evident, the authors say, that these three cases prove nothing; yet the results were so striking that it seemed desirable to make this report in order that others with more clinical material might investigate the matter further.

**The Elimination of the Digitalis Bodies,** by R. A. Hatcher. See this _JOURNAL_ for July 5, p. 50.

**Venous Blood Pressure as Influenced by the Drugs Employed in Cardiovascular Therapy,** by J. A. Capps and S. A. Matthews. See this _JOURNAL_ for July 5, p. 50.

**Lactic Acid Spray for Diphtheria,** H. A. Wood states that a spray of lactic acid bacilli was recently used in available diphtheria cases with a view to clearing up refractive diphtheria carriers and in an attempt to find, for spraying, some organism which is not foreign to human tissues and not regarded as pathogenic. The success was rapid and marked, but with a few trials no definite statements can be made. The suggestion is offered that others try this spray, as the staphylococcus is now being used for overriding local bacterial infections; so that its usefulness may be measured or the inadvisability of its employment demonstrated.

**Tonsillitis Following Use of Staphylococcus Spray,** C. M. Davis reports this case, in which the patient was a girl eighteen years old.

**An Anomalous Case of White Spot Disease,** by H. H. Hafner.—See this _JOURNAL_ for July 5, p. 42.

**Idiopathic Atrophy of the Skin; with Report of a Case,** by H. G. Irvine.—See this _JOURNAL_ for July 5, p. 42.

**Adaptation of the Cinematograph to the Study of Embryology and Tissue Growth,** J. E. McWhorter and P. Prime, Jr., describes a method they have evolved for adapting the cinematograph to the microscope for the purpose of photomicrography, and state that from the results thus far obtained with it they feel warranted in assuming that the method is at least practical and capable of much further elaboration. The embryos, as well as the tissues used in their experiments, were those of the chick, the pictures being taken in different stages of development.

**Neuroma Cutis (Dolorosum),** by M. L. Headingsfield.—See this _JOURNAL_ for July 5, p. 42.

**The Newer Cutaneous Mycoses,** by E. D. Chipman. See this _JOURNAL_ for July 5, p. 43.

**Turpentine Poisoning Producing a Scarletoid Rash,** J. D. Blackwood, Jr., describes this apparently unique case. The patient, a girl of twenty, presented a scarlatinoid rash, in addition to the ordinary symptoms of turpentine poisoning, forty-eight hours after the ingestion of oil of turpentine. The toxic dose was very small (only fifty-five minims in twenty-four hours). Desquamation began three days after the appearance of the rash. The rash had to be distinguished from that of any of the diseases subject to quarantine.

**MEDICAL RECORD.**

_August 9, 1913._

**The Problem of the Social Evil Considered in Its Social and Medical Aspects and in Its Relation to the Problem of Race Betterment,** J. E. Mears says that to control prostitution its existence must be fully recognized. Its social and its hygienic conditions demand the earnest efforts of the social worker and the medical profession. Being hostile to the best interests of the community, it calls for restraint by the law, which should be applied in a humane and rational manner. This would seem to be best accomplished through a commission appointed preferably by the State, the constitution of which (of paramount importance) should include both men and women of experience and judgment. To such a commission could safely be entrusted the formulation of such plans of care and control of prostitutes as
would contribute to their betterment and the protection of the community. Through it the blackmailing policeman and the grafting politician would be eliminated, and, with the powerful assistance of the national government, the white slave traffic would be destroyed. No valid reason can be urged against the maintenance of an assumed freedom from disease of the public prostitute by compulsory examination and treatment under plans instituted by the commission.

Authoritative Diagnosis of Gonorrheal Stomatitis.—J. B. Stein points out how obscure and difficult the diagnosis of this condition is. In the urethra the number of cocci resembling the gonococcus is small, but the reverse of this is true in the mouth and nasopharynx. At the present time the finding of a living contagium plays the chief rôle in the diagnosis. The fact that the meningococcus and other forms of cocci are to be found in the secretions of the nose must arouse much caution. The morphological and staining characteristics of the meningococcus and gonococcus are very similar, and it is only possible to distinguish them from each other by cultural methods, the conclusions from which should be confirmed by the use of the sugar litmus serum agar media of von Lindeitschm.

Personal Experience with Neosalvarsan.—The following are the conclusions reached by T. S. Van Riepl: 1. Neosalvarsan is preferable to salvarsan on account of its equal efficiency, lesser toxicity, and easier mode of administration. 2. In an early diagnosis of syphilis we can prevent the appearance of secondaries by the timely injection of neosalvarsan. 3. The doses in children and infants should be based on body weight—preferably 0.015 gramme for every kilogramme of body weight. 4. Neosalvarsan is not a positive cure for syphilis, but is superior to mercury, potassium iodide, or mixed treatment, and should always be resorted to when lesions persist under such treatment. 5. The intravenous is preferable to the intramuscular injection, on account of the severe pain and frequent abscess formation and sloughing produced by the latter. 6. The introduction of a small amount of air into the vein has no deleterious effect upon the patient. 7. The intervals between the injections should never be less than one week.

Indicanuria, the Feces, and the Sulphates of the Urine.—J. C. Warbick reports the results of the examinations in eleven individuals. First, a meal consisting chiefly of beefsteak was taken, along with coffee and bread; after which an examination of the urine was made in each instance, or after every meal, and the results were tabulated from time to time. At each examination the amount of the feces passed was noted, and also their color and odor, as tending to have some part in the formation of indican in the urine, and also as having some influence on the amount of sulphates, which were remarkably high on some occasions—far beyond the amount of chlorides and phosphates. The highest point the sulphates reached was the unusual figure 50,775, and the lowest, 1,155; thus making a wide range. Indican was found in eight of the urinary examinations, while twice it was absent under circumstances when it might have been expected, namely, a high specific gravity and a large amount of sulphates. At none of the other examinations when all the conditions necessary for its formations seemed present was the amount of indican high.

Pneumonia: Immediate and Contributing Cause of Death; Rational Treatment.—W. C. K. Berlin has made investigations which indicate that the more profound the infection and toxemia, the more viscid is the blood stream. The successful treatment bears a close relation to this condition, and the first effort should be directed to the prevention of this viscosity, or so much so as to relieve the great strain which it imposes on the heart until the regular cycle of the disease has passed. One of the early diagnostic features in pneumonia is the deficiency of chlorides in the urine. It would seem reasonable to supply this evident lack of chlorides in the blood and tissues, and this is easily accomplished by giving intravenously large amounts of isotonic saline solution at more or less frequent intervals. This also dilutes the blood and, in addition, stimulates the kidneys and facilitates the elimination of toxic material. Some two years ago the author introduced to the profession the safe administration of an iodine solution intravenously as a treatment for tuberculosis and bronchial affections. Since then he has noted, in experiments upon blood, that this solution, added in small quantities to a large amount of blood, prevents coagulation. To the isotonic saline solution he has therefore added this iodine solution, to which were added creosote and quaiacol, for their anesthetic and germicidal action. Although the number of patients so treated has been too small to be conclusive, everyone has recovered, in spite of the fact that several had been given an absolutely bad prognosis by competent consultants.

American Journal of Tropical Diseases and Preventive Medicine.

Trypanosoma Americanum in Naturally Infected Animals.—Foster M. Johns reports having found the Trypanosoma americanum in the blood of each of forty-three adult cattle and in two out of seven yearlings coming from widely separated localities in the United States. The number of trypanosomes found varied from two to twenty-one in each ten c. c. of the whole blood. Different forms analogous to the "male" and "female" specimens described for other trypanosomes could be demonstrated.

Surgical Treatment of Elephantiasis.—Rudolph Matas, after discussing the procedures advocated by various surgeons in elephantiasis and elephantoid states dependent upon chronic obstruction of the lymphatic and venous channels, reports, with H. B. Gessner, two cases in which Kondoleon's operation was performed. This procedure consists in the free excision of the fascia lata in the thigh and leg and suture of the skin directly over the underlying muscles, and is intended to establish new permanent anastomotic channels between the supraaeroneurotic and the infraaeroneurotic lymph spaces. In the cases reported, both operated in the leg only, encouraging results were obtained: in the first case the benefit has been maintained for five months. Matas advises others to give the method a trial, when the occasion presents.
The Address of the President.—Dr. H. A. McCullum spoke in part as follows: It was his inten-
tion to speak plainly on many matters affecting the profession. He urged a more active interest in the work of the association. It had done great service in doing away with provincialism and inaug-
urating great reforms of inestimable benefit to the profession and the public generally. With every practitioner in Canada a member, greater and more beneficent results could be obtained. More funds were necessary, however, to rescue the association from the exploitation and the commercial enterprise of certain drug houses. The chemical industry of Germany was carefully organized and it was diffi-
cult to know what to accept and what to reject. Trained and scientific censors were needed to give advice and to assist in shaping legislation to pre-
vent the sale of nostrums. The promise of Hon. R. L. Borden that a portfolio of public health would be instituted in the near future had created unbounded satisfaction among the members of the profession. A pure food law or federal control of vaccines, sera, and drugs was impossible with-
out this. Doctor McCullum praised on the whole, the report and work of the Carnegie Foundation, but thought that a mistake was made in exagger-
ating the value of the German methods of medical teaching. In his opinion the British methods of medical training produced the best practical men, which was, after all, the main object of such teach-
ing. Attention was drawn to the fact that the med-
ical student of to-day was burdened too much with scientific subjects and laboratory work, with-
out being grounded sufficiently in the fundamentals. This was a mistake, and the general practitioner suf-
fered. The larger proportion of students graduat-
ing to-day were going to specialize in surgery, and there was a grave danger that this branch of med-
ical science would crowd the practice of medicine into the background. This was not in the best in-
terests of the profession as a whole, nor of the pub-
lic. The lack of knowledge of the value of med-
icine made the practitioner, as well as the public, a victim of the nostrum peddler.

Doctor McCullum advocated the annual exami-
nation by competent physicians of every adult. School children were examined periodically, but the adult never consulted a doctor until sickness compelled him. Insurance companies had adopted a plan of examining their clients annually, and in his judgment it would be good business if all men and women underwent a thorough periodical ex-
amination. The necessity for higher degrees in sur-
gery in Canada and the United States was dealt with. The profession generally would be improved thereby. Incidentally the low fees prevailing in many parts of the Dominion were referred to and he expressed hope that there would be a general leveling up in this respect. He was of the opinion that more publicity should be given to the achieve-
ments of medical science. Certain branches of the profession had followed this out with much success. Great publicity had been given to the results of vaccination in the prevention of smallpox, and the same results would follow if wider publicity were given to vaccination against typhoid fever. The inroads of tuberculosis had been made public and the support of the people enlisted to stamp out this disease. Similar methods should be adopted in the case of cancer and other diseases. That the pro-
fection should not be an arm of the civil service was most emphatically stated. If it were, the public would not be protected against its own gigantic credulity, nor the profession purged of its abuses. A demagogue might arise at any time to attack the profession, and it was best to be armed and ready.

Dr. Lewellys F. Barker, professor of medicine at Johns Hopkins University, Baltimore, gave the address in medicine. The address dealt with the nerve supply of the internal secretory organs and of the smooth muscles, but inasmuch as it was deliv-
ered extemporaneously and illustrated by diagrams thrown on screen, this necessitating the turning out of the lights, it was impossible to take adequate notes of it. The address was of a most instructive and interesting nature and as Doctor Barker an-
nounced that it would be written out and handed in to the secretary of the Canadian Medical Associa-
tion, it will doubtless be published in the journal of the association, where medical readers will be afforded the opportunity of studying an intricate subject presented by a master.

Dr. T. S. Cullen, of Johns Hopkins University, Baltimore, gave the address in gynecology. This address mainly discussed the great importance of the early diagnosis of cancer and the need for edu-
cating the general public, and especially women, with regard to its early symptoms. Doctor Cullen em-
phasized the point that cancer, contrary to popular belief, is not a blood disease, neither is it incurable when treated properly at a sufficiently early date. In order to gain this result the message must be carried directly to the people. A brief sketch was given of the campaign on popular lines against can-
cer initiated at the Congress of Surgeons of North America, held in New York in November, 1912, and since inaugurated on a large scale. It was pointed out that after considerable deliberation it was decided, not only to interest daily and weekly journals and popular magazines in the mat-
ter, but to employ a lay rather than a medical writer for the purpose of propagating knowledge of cancer among the laity. Mr. Hopkins Adams was chosen as the writer who would best ful-
fil this mission. According to Doctor Cullen the results of this popular campaign had already been most successful. A strong impression had been made throughout the country by Mr. Adams's writ-
ings and in consequence many persons had been treated with success who otherwise would have al-
lowed the disease to gain so strong a foothold that remedial or curative measures of any kind would have been futile. Regarding the duty and responsi-
bility of the medical man in the early diagnosis of cancer, the need for an adequate supply of good
surgical pathologists was dwelt on. Not only must every surgeon have a thorough grounding in surgical pathology, but every hospital must have a skilled surgical pathologist on its staff. Doctor Cullen recommended that Canada should follow the example set by this country and inaugurate a popular educational campaign on similar lines.

Dr. I. Alexander Hutchison, of Montreal, gave the address in surgery, taking as his subject fractures and their treatment. A somewhat exhaustive review of the treatment of fractures was given and the report on fractures issued recently by the committee appointed by the British Medical Association to investigate into the matter was referred to in eulogistic terms. Doctor Hutchison also highly praised a partial report on the same subject, which has just been published in the United States, and which held out the promise of greatly adding to our knowledge of fractures and their treatment. The misuse of X rays in courts of law was alluded to and it was pointed out that skiagrams without skillful interpretation were not only useless but in a high degree harmful, and in the opinion of the speaker the medicolegal section of the association should investigate and report on the position of the medical profession with regard to this question.

An event of the meeting was the presentation of the committee nominated by the Canadian Association for the Prevention of Tuberculosis to investigate and report upon the so-called Friedmann cure. At first the committee consisted of five members, but afterwards added to itself those physicians who had under observation the cases treated. The number inoculated by the Friedmann serum were, in Montreal, 19; in Ottawa, 18; in Toronto, 81; in London, 35. The committee reported as follows: "As a result of our observations from March 11 to the present time the following conclusions seem justifiable";

1. The inoculations have neither constantly nor frequently been followed by marked changes in the clinical course of the disease. 2. The cure or progress toward cure claimed by Doctor Friedmann for the treatment has neither constantly nor frequently been taken place in the time during which these cases have been under observation. 3. Thus, upon investigation, the committee finds that the results have been disappointing and that the claims made for his remedy by Doctor Friedmann have not been proved, and that nothing has been found to justify confidence in the remedy. Signed, Professor J. G. Adami, Professor J. J. MacKenzie, Dr. A. H. Caulfield, Dr. E. S. Harding, Dr. John W. S. McCullough, Dr. W. E. Ross, Dr. J. H. Elliott, and Dr. George Porter.

Dr. Charles H. Hodgetts, of Ottawa, a member of the committee, was averse from signing the report and gave as his reasons for his aversion from doing so that Doctor Friedmann had promised to reveal to the members of the committee the composition of his remedy. Not having kept his promise, Doctor Hodgetts considered that it nullified any value the report might have had, and consequently thought it would be useless to sign it.

In the Section in Public Health, under the chairmanship of Dr. Helen MacMurphy, the report of the special committee on medical inspection of schools, compiled by D. John Stewart, of Halifax, was read in his absence by Doctor Fidlar, of the London Institute of Public Health.

Doctor Stewart, after passing in review the work being done in all the provinces of Canada, and especially remarking on the sympathetic interest taken in the work by Doctor Pyne in Ontario, stated that he was forced to conclude that the work was yet in its elementary stage. While there had been progress in the cities, owing to the efforts of the few, there was still apathy shown in the smaller places, and this condition of affairs would continue until some definite system was worked out that would constitute a national standard. For this reason therefore there was need for a national public health service that could deal with such questions as immigration, sanitation of factories, control of diseases, and adulteration of foods along with the medical inspection of schools.

In the discussion that followed the reading of this paper, Doctor Barty, of British Columbia, expressed the opinion that the work of medical inspection of school children in Canada was wrongly conceived and carried out. Children were shut up at the very time they needed the vigor giving sunlight and air. What he thought was needed was out of door workshops, leaving the regular school curriculum to be picked up later. Doctor Halfpenny, of Winnipeg, in discussing the question as to whether it was best for the control of medical inspection of schools to be placed in the hands of the school authorities or left to the boards of health, said that arguing from the experience of Great Britain and of the United States in this matter, he thought that such control should be placed in the hands of the school authorities. The chief reason he gave for the conclusion was that in the United States and in Canada the boards of health were dominated by local politics and that the school boards were comparatively free from this pernicious influence. Also the line of reasoning afforded a strong argument for federal control, as by this means inspection of school children would be wholly removed from the sphere of local politics. Professor Adami, of Montreal, emphasized the importance of earnest cooperation between the school boards and the boards of health. A committee was appointed to frame a report on this subject, the main recommendation of which was that for the present the inspection of children be done by an appointee of the school board, working in conjunction with the medical officer of health. At the end of a long debate it was decided to leave the matter over for another year, and have it take a prominent place on the programme of the next convention.

Another important discussion that took place in the Section in Public Health was that dealing with venereal diseases. Papers in reference to the solution of the venereal disease problem were read by Dr. H. W. Hill, of London, and by Dr. F. A. Clarkson, of Toronto. Doctor Hill, compared to some extent syphilis with typhoid fever, and in the course of his remarks said: "If it was criminal for a city to allow its citizens to drink polluted water it was yet more criminal in his opinion to allow venereal diseases to spread, destroying the race and blasting future generations. While it was a moral
question in one respect, it was a physical matter involving the future well being of the race, and as such should receive the legislative attention that its great importance deserved.

Doctor Clarkson in his paper advocated segregation as a means for preventing the spread of the disease.

In the discussion which followed the reading of these papers, Doctor Adam advised that the question of morals should be disregarded by the medical profession when attacking the problem of venereal disease, not because the profession was not heartily in accord with the views of the moralists, but because the view of the medical profession was purely a physical one. Doctor Dill argued that moral suasion had been tried for centuries without effect and that it was now necessary that legislation be introduced which would control the spread of syphilis and gonorrhoea. Doctor Hutchinson, of Westmount, thought that what moral suasion could not accomplish, legislation would not. Dr. R. E. Wodehouse said that in Fort William there was a segregated area and that this system tended to keep down the spread of venereal disease. Doctor Halpenny, of Winnipeg, disagreed with this view in toto and held that where there was a segregated area the disease was spread among shop girls and factory girls. Prostitutes, as a rule, were careful to avoid disease, since their earning powers depended upon the state of their health. He declared that in his opinion segregation always was and always must be a hopeless failure. He suggested that hospitals and jails be required to report on all cases of venereal disease coming under their notice.

A committee was appointed to deal with the subject and report thereon. The most important recommendation made in this report was to the effect that provincial boards of health be asked to have venereal diseases added to the list classed as reportable infectious diseases. A certain amount of doubt was expressed as to the probability of this suggestion being considered practicable, but it was pointed out that as in the case of tuberculosis a beginning must be made. Though few cases might be reported at first there would be more in time.

Doctor Wilson said that in Saskatchewan syphilis was now a reportable disease, while Doctor Halpenny, of Winnipeg, saw an advantage in the recommendation that it would awaken legislators to the problem that has arisen in the country and would probably start them in search of a solution.

Dr. Lewellys F. Barker, of Johns Hopkins University, Baltimore, gave an address on mental hygiene. He said in part that by this term was meant the conservation and improvement of mental health to make men think better, act better, and become better than now. The imbecile, the criminal, the prostitute, the insane, were so because they had to be. Their minds worked that way. The majority had been born with a bad brain and acted as their brain directed. While others, though born with a good brain, because of some deleterious act acted wrongly or criminally. Two sciences were dealing with the problem of mind improvement. One was the science of eugenics and the other ethnics. The advocates of the first believed largely in heredity and were endeavoring to bring children into the world equipped with good brains. The other school believed that environment played the larger part in the development and expression of brain power. Both schools were of equal importance and there should be no quarrel between them. Doctor Barker outlined the recent campaign for the promotion of mental hygiene in the United States, which was intended to make the public, the doctors and the lawmakers recognize the importance of the question. Criminality, prostitution, immorality and the like were due to bad brains, and by enacting proper laws to prevent the marriage of the minds that prevent the spread of diseases that affect the physical well being of the coming generation, much of the evil could be stamped out. The benefit of institutional training was shown and highly recommended by Doctor Barker. He believes that psychiatric clinics should be held frequently, and that school teachers should be educated to recognize exceptional children and segregate them or have them placed in institutions where their mental well being would be assured. Such a campaign undertaken in Canada ought to produce as good results as it had produced in the United States.

Dr. George Nasmith, of Toronto, pointed out, in a paper dealing with milk supplies, the need for absolute cleanliness from start to finish. There was need for regular inspection of milk by municipalities and in addition farmers should be encouraged to use the "cow test" to insure quality. The only way of making milk an entirely safe article of diet was by pasteurization. Doctor Bryce, of Ottawa, suggested that municipal control of milk supplies would be a move in the right direction. Dr. H. W. Hill, of the London Institute of Public Health, gave an interesting account of health statistics, secured from the parents of 8,000 children attending the schools of London. He computed that each child in the city had 2.5 infections during the ages from five to nineteen. Taking these figures as typical of the whole province, he concluded that during each year there were 200,000 cases of infectious diseases which at the very low estimate of two dollars per case would mean that the province expended $600,000 annually for the care of these cases. The monetary loss was great, not to mention the deaths and suffering following. Medical men should do all they possibly could to prevent the spread of these preventable diseases. Every year there were, at least, 15,000 cases of scarlet fever in Ontario, 37,500 cases of measles, and 27,000 cases of whooping cough, which was the most dangerous of them all.

Dr. Helen MacMurchy, of Toronto, gave a popular and instructive lecture at a public hall in London on the evening of June 26. Dr. MacMurchy said that there was a high standard of national health in Canada at present. This fact was attested by the protest of a number of English doctors recently when complaint was made that some of the immigrants were not physically fit. It was not to be expected, they said, that they should equal the native born Canadian in physique. How to conserve this high standard was the problem at present facing the nation. The observation of a few simple rules was all that was required. Fresh air, good food, a good water supply, cleanliness, and
sleep were all that were needed to preserve the health of the nation, but without these essentials national health was impossible. Doctor MacMurchy cited many instances to show the progress made by the medical profession in matters of sanitation. England had led in this respect and had practically taught the world sanitation. The making of the Panama Canal had been rendered possible only by the doctors. France had tried the project and failed, not because her engineers were inferior to those of America, but because disease had stricken the laborers. Sanitation had practically wiped out fever in the canal zone. Dr. MacMurchy referred to the subject of the care of the feebled minded. The Province of Ontario should look after these, as they were unable to care for themselves. They should not be allowed to marry to bring into the world others similarly afflicted.

Symposia on Diseases of the Stomach and on Diseases of the Thyroid were introduced respectively by Dr. Alexander McPhedran, of Toronto, and by Dr. A. J. Ochsenre, of Chicago. Dr. Frank Billings, of Chicago, conducted a medical clinic and Dr. John B. Murphy, of Chicago, gave a clinical lecture, illustrated by lantern slides. Dr. Billings attacked the present methods of handling vaccine in the United States. He said that drug firms manufactured vaccines for nearly every known disease and even went so far as to combine a number of cultures of various kinds to make a vaccine supposed to act as a sort of cureall for disease. He was a believer in the use of vaccine. It was without question valuable in the treatment of some diseases, but the manufactured vaccines were often entirely unsuited for the purpose for which they were sold and were likely to have serious effects on the patients. He urged doctors to prepare vaccine for themselves when a case seemed to demand its use.

The executive committee of the Canadian Medical Association was elected as follows: Dr. F. P. Drake, of London; Doctor MacKidd, of Edmonton; Doctor Primrose, of Toronto; Doctor Small, of Ottawa; Doctor Adams, of Montreal; Doctor Reeve, of Forest; Doctor Halpenny, of Winnipeg; Doctor McKeehnie, of Vancouver; Doctor Brett, of Bauff; Doctor McNeill, of St. Johns; Doctor Mader, of Halifax; Doctor Park and Doctor Whitelaw, of Edmonton, and Dr. F. N. E. Starr, of Toronto. St. John, New Brunswick, was chosen as the next place of meeting, and Dr. Murray MacIrvine, of St. John, was selected for the presidency next year.

Book Reviews.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

This publication gives a very clear and interesting presentation of the bacteriology of infectious diseases. Although not a textbook on bacteria it gives good descriptions of them and a well coordinated picture of the methods by which the various diseases and their complications present themselves. The chapters take up the diseases due to pathogenic cocci, bacilli, vibrios, sprochetes, yeasts, moulds, and plasmodies, and a final one discusses those infections of doubtful origin. The two most extensive articles are the one on the plague and cholera, while others give much in detail concerning mala fever, yellow fever, recurrent fever, typhus, and smallpox. Rabies is also given considerable space. From the above it will be seen that the tropical side is somewhat emphasized, but in these days tropical diseases have plenty of opportunities to lodge in our own lands and we should be ready to recognize them. The numerous illustrations are very good and the book can be recommended highly.

Although the title would indicate that this book deals with general pathology in the usual way, one is very agreeably surprised to note the way in which the treatment of the subject differs from other textbooks. There is little said on histological pathology, and practically no illustrations, the authors taking it for granted that the reader is more or less familiar with that side of the question. The subject of pathology is treated from the important viewpoint of physiology, in order to depict clearly the lack of coordination between the normal activities of the component parts of the body in diseased conditions. The various topics are dealt with by different men in a very able manner, the valuable information being presented in an interesting way. As is stated by the editors, this book is intended primarily for the advanced student and practitioner, not for the beginner. It is one that would be of the greatest value to those who wish to perfect their knowledge of the important correlation of pathological conditions with disturbances of physiological functions.

The Journal has frequently referred with approval to this excellent series, and unless one were to go into a detailed review of the contents, there is little that need be added to the expressions of opinion previously given. As will be noted, Dr. Frank Billings and Dr. J. H. Salisbury remain in charge of the medical portion of the series, and Dr. John B. Murphy, of the surgical, and as always before, these editors have made excellent selections of material—certainly no easy task when one takes into consideration the vast amount of this to be gone over. The works and articles are so well written and the discussions so clear that the student will have every facility for learning the characteristics of the infectious diseases in the medical volume we note, for instance, an account of the investigations of Anderson and
Goldberger resulting in the identification of Brill's disease as a form of typhus fever. It has thus been demonstrated that typhus fever, instead of being the exotic plague that it has almost universally been considered, has actually been endemic in this country for many years. In connection with this advance in our knowledge of the disease the authors very properly give the following caution: "It is important to recognize the existence of a problem of which he here-tofore has been unaware; it also makes it necessary for the clinician to revise the classical conception of typhus, just as it has revised conceptions of smallpox and yellow fever." In the surgical volume we find the latest improvements and developments in anesthesia, and much attention is devoted to intestinal surgery, in which so much of interest has recently attracted the attention of the surgeon. The author who undertakes to keep up to date, and the plates and diagrams are of material service in elucidating the text.

This little work contains a collection of 350 diagnostic tables placed perpendicularly opposite one another for purposes of comparison. Many textbooks of practice and diagnosis contain such, but none in such profusion as is offered in the present book. Not only is this mode of embodiment helpful at a glance, but the use of two or three columns makes an obvious advantage to the practitioner, but it enables the student to test his knowledge and to accustom himself to differential diagnosis, which plays such an important part in clinical work.

Register of Purchases and Record of Amount Used of Alkaloid Cocaine or its Salts, or Alpha or Beta Eucaine or certain other similar Compound or Product of Which Cocaine or Eucaine or their Salts May Be an Ingredient. New York: Wisner & Dor- mitzer, New York.

This is a very timely and practical register. It certainly will assist the physician to overcome the difficulty thrown into his way by the law referring to the sale and use of cocaine and its salts in force since June 10, 1913. The arrangement is a very good one as the double form of the back makes its use very easy. We can well recommend it to the physician.

Consumption in General Practice. By H. Hyslop Thom- son, M.D., D. F. H., Medical Superintendent to the Liv- erpool Sanatorium and Nursery (Frowde, University Press) and Hodder & Stoughton, 1912. Pp. x-v-335. (Price, $5.50.)

The object of this book is stated by the author in the preface to this, the second edition of the work. To quote directly, "An effort has been made to maintain the aim of the first edition and to provide a short and concise study of the present day problem of consumption as it presents itself in general practice." Despite the worldwide attention that has been given to the topic, the profession is still culpable in failing to recognize the disease in its incipiency. Too often the doctor in general practice superficially diagnosticizes the condition as dyspepsia, asthma, neurasthenia, general debility, run down constitution, or something similar, when in fact the unfortunate is already in the early stage of tuberculosis. This book provides the first sentence in the book of particular importance.

The author states, "It is now becoming fully recognized that the successful treatment of pulmonary tuberculosis depends to a great extent upon the prompt recognition by the medical officer that in the consulting room no more difficult problem presents itself than the immediate diagnosis of early tuberculosis of the lungs." He further states that in all cases when a tentative diagnosis of commencing tubercu- losis of the lungs should be made, the diagnosis should be reported to the patient, coupled with close and conscientious observation and a generally optimistic attitude on the part of the doctor; these in the vast majority of instances over- come the patient's fears, and, for it is now generally known that many recover and that the earlier it is recognized, the greater the probability of recovery. The author deals with the subject under the headings, Diag-

osis, Prognosis, and Treatment, and does so in a very practical way, and especially valuable and suggestive are the pointers on treatment. The book, in no sense epoch making, is merely a well balanced statement of facts which, if possessed by every practicing doctor and lived up to by him, would rapidly aid in the solution of the tremendous problem of tuberculosis, which touches all the shores of activity: Educational, sociological, medical, etc.

Clinical Electrocardiography. By Thomas Lewis, M.D., D. Sc., F. R. C. S., R. Assistant Professor on Cardiac Pathology, University College Hospital, Physic- ian to Outpatients, City of London Hospital. Lon- don: Shaw & Sons, 1913. Pp. vii-120.

This is a timely little book, but one which will appeal to the specialist and more especially to a limited number of those who have been able to procure the various graphic methods for the study of cardiovascular diseases. From the standpoint of the electrocardiogram and its inter- pretation, the work is rich in suggestiveness and illus- tration, but as an aid to those who wholly lack familiarity with the instrument and its technicalities the book is lacking in detail. It is essentially a further amplification of another book of Doctor Lewis's on Clinical Diseases of the Heart Beat. From the fullness of his experience, he is able to state convincingly that graphic methods are as paramount to all others in the intimate study of diseases of the heart and bloodvessel system. He states: "Those cardiac patients are few in whom an electric examination is superfluous, and in a large and increasing percentage of cases the records profoundly modify our conception of the conditions with which we deal. The time is not distant when no hospital which undertakes the care of many of these patients may neglect the string galvanometer, if it is to rank amongst institutions whose design is proficiency.

This volume is intended to save the physician trouble in working out combinations of food for diabetics, and also acts as a guide to the cook in preparing the same. Some one hundred and thirty pages are devoted to recipes, each one giving the proportion of allulose, fat, carbohydrates, and the resulting calories. A list is given of the above values of many different foods, and then nearly two hundred and fifty pages are filled with menus for the different meals during the day; the object being to afford as much variety as possible. For one who is in the medical profession interested particularly in dietetics this book would be distinctly valuable.

Official News.

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending August 12, 1913:

Derivaux, R. C., Assistant Surgeon. Upon receipt of instructions from Surgeon R. H. von Exdorff, directed to proceed to Ann Arbor, Mich., for such other points in the State as may be designated, for the control of the prevalence of malaria. Eager, J. M., Surgeon. Re- lieved from temporary duty in the Hygienic Labora- tory, effective August 23, 1913, and directed to proceed to Philadelphia, Pa., for duty as sanitary inspector with the Public Health Service; upon completion of this duty to pro- ceed to Naples, Italy, for duty in the office of the American Consul, Fricks, L. D., Surgeon. In compli- ance with request of State health officers, directed to visit certain places in Kandahar, Afghanistan, as a part of sanitary expedition. Robertson, H. McG., Passed Assistant Surgeon. Granted one month's leave of absence from August 21, 1913. Robertson, H. R., Acting Assistant Sur- geon. Detailed to assist Senior Surgeon H. R. Carter in the investigation of malarial conditions in the State of North Carolina. Stiles, W. V., Professor. Detailed to assist the annual faculty meeting in various counties in North Carolina, from August 25th to September 6th, and on completion of this duty to proceed to Birm-ingham, Ala., and to the Sixth Congressional District of
Alabama between September 9th and 20th, to lecture on rural sanitation and the prevention of disease. Vice-Admiral Harrard, to proceed to, and visit, Birmingham, Ala., and to the Sixth Congressional District of Alabama for the purpose of delivering lectures on rural sanitation and the prevention of disease.

**Warner, H. J., Passed Assistant Surgeon.** Relieved from temporary duty at Typhoid Fever Hospital, Washington, D. C., and directed to proceed to the New Orleans Quarantine Station and report to the medical officer in charge for duty and assignment to quarters.

**Promotions.**

Assistant Surgeon Charles M. Fauntroy promoted and commissioned as passed assistant surgeon, effective June 13, 1913.

Assistant Surgeon Hermon E. Hasseltine promoted and commissioned as passed assistant surgeon, effective August 7, 1913.

Assistant Surgeon James P. Leake promoted and commissioned as passed assistant surgeon, effective August 30, 1913.

Assistant Surgeon Lawrence Kolb promoted and commissioned as passed assistant surgeon, effective August 5, 1913.

**Boards Convened.**

Board of commissioned medical officers convened to meet at the Bureau, Washington, D. C., at 1 to 12 o'clock, a.m., August 9, 1913, for the physical examination of M. A. Hunnewell to determine his fitness for appointment as constructor in the U. S. Revenue Cutter Service. Details for the board: Surgeon Taliaferro Clark, chairman; Passed Assistant Surgeon Warner, secretary.

Board of medical officers convened to meet at Providence, R. I., for the reexamination of aliens Nicola and Angelo Ibello. Details for the board: Surgeon S. B. Grubbs, chairman.

**United States Army Intelligence:**

- **Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Army for the week ending August 16, 1913:**

  **Anderson, J. B., First Lieutenant, Medical Reserve Corps.** Ordained to Fort Caswell, about August 29th, for temporary duty. **Armstrong, John M., First Lieutenant, Medical Reserve Corps.** Relieved from active duty in the Medical Reserve Corps, to take effect at once, and so much of paragraph 13, Special Orders No. 157, July 26, 1913, is amended accordingly. **Barker, John R., Captain, Medical Corps.** Ordered to Washington, D. C., with insane soldiers from Letterman General Hospital, San Francisco, Cal. **Bigham, W. N., Major, Medical Corps.** Returned on academic leave of August 8th. **Blanchard, R. M., Major, Medical Corps.** Ordered to Fort Niagara, N. Y., for duty with the 29th Infantry until the completion of field service. (About August 16th to October 1st.) **Chappell, S. L., First Lieutenant, Medical Corps.** Left Fort Bliss, Texas, on August 7th, for temporary duty at Columbus, New Mexico. **Collins, Christopher C., Major, Medical Corps.** Relieved from duty at Fort Screven, Ga., to take effect upon his return to that post after the completion of his present duties with the Provisional Cavalry Brigade at Winchester, Va., and will then proceed to the Presidio San Francisco, Cal., and report in person to the commanding officer of that post for duty. (On August 22, 1913, as amended accordingly.) **Deibert, Bader—In Birdboro, Pa., on Tuesday, August 5th, Dr. Edward J. Deibert, of Hellertown, and Miss Flora Bader.** **Kennedy-Dugan.**—In South Atleboro, Mass., on Monday, August 11th, Dr. William Bernard Kenney, of Providence, R. I., and Miss Mary Elizabeth Dugan. **Powers—Byrne.**—In Los Angeles, Cal., on Wednesday, August 6th, Dr. L. M. Powers and Mrs. Mary R. Byrne. **Walsh—Yates.**—In Brockton, Mass., on Wednesday, August 6th, Dr. Daniel J. Walsh and Miss Inez Yates.

**Died.**

**Allen.**—In Brooklyn, N. Y., on Friday, August 8th, Dr. Emma T. P. Allen, aged sixty-eight years. **Edwards.**—In Atlanta, Ga., on Tuesday, August 5th, Dr. G. O. Edwards, aged twenty-eight years. **Fuller.**—In Washington, D. C., on Tuesday, August 5th, Dr. Fred E. Fuller, aged sixty-three years. **Garrett.**—In Lithia Springs, Ga., on Tuesday, August 5th, Dr. C. C. Garrett, aged sixty-three years. **Green.**—In Charlottesville, Va., on Saturday, August 29th, Dr. Bennett Wood Green, aged seventy-five years. **Gregory.**—In Seaforth, N. J., on Monday, August 11th, Dr. Andrew J. Gregory, aged eighty-four years. **Grice.**—In Bryan, Texas, on Wednesday, August 6th, Dr. S. N. Grice, aged fifty-eight years. **Harris.**—In Richmond, Ky., on Sunday, August 10th, Dr. Giles Harris, aged sixty-eight years. **Hotaling.**—In Syracuse, N. Y., on Friday, August 8th, Dr. Albert S. Hotaling, aged forty years. **Iralson.**—In St. Louis, Mo., on Wednesday, August 6th, Dr. Abra- ham Iralson, Field Hospital No. 2. **Doerr.**—In Woodstock, N. J., on Tuesday, August 12th, Dr. Emerson Pulm McGeorge, aged forty-two years. **Miller.**—In Bloomington, Ill., on Tuesday, August 5th, Dr. W. T. Miller, aged eighty-five years. **Minor.**—In Westminster, Mass., on Saturday, August 16th, Dr. John Cran- nell Minor, aged seventy years. **Mitchell.**—In New York, on Tuesday, August 12th, Dr. Hurbard Winslow Mitchell, aged seventy years. **Morrill.**—In Chicago, on Monday, August 11th, Dr. A. W. Morrill, aged thirty-eight years. **Morril.**—In Fort Preble, Me., on Saturday, August 9th, Colonel Harry O. Perley, Medical Corps, United States Army, retired, aged sixty years. **Shaw.**—In Denver, Colo., on Tuesday, August 8th, Dr. Robert T. Shaw, Medical Corps, United States Army, retired, aged sixty years.
AN ANALYSIS OF FIVE HUNDRED FATAL MEDICAL CASES IN THE TROPICS,
With the Clinical Diagnosis in the Light of Autopsy Findings.*

By W. E. Deeks, M. A., M. D.,
Canal Zone, Panama,
Chief of Clinic, Ancon Hospital;
And W. G. Baetz, M. D.,
Canal Zone, Panama,
Physician to Ancon Hospital, Canal Zone, Panama.

When Cabot, in 1910, published his splendid paper entitled A Study of Mistaken Diagnoses, based on an analysis of 1,000 autopsies and a comparison with clinical findings, the medical staff of this hospital was very much interested, and profited accordingly. Cabot's study is rather an original conception and of courageous veracity, compared with the average paper, which usually speaks of success achieved and carefully avoids mentioning any serious failures encountered. Two years later, when the same author published a further study on similar lines in 1912, under the title of Diagnostic Pitfalls, the value of such studies, both to the patients in our care and to ourselves as a profession, was brought home, and it was decided to undertake a study of a number of consecutive diagnoses in fatal cases coming to autopsy here in the tropics.

Our aim, in the following analysis, has been to ascertain, primarily, the errors made by the medical staff of this hospital in determining the actual cause of death among a population in the tropics where the negro and mulatto outnumber the white in a ratio of about 6 to 1. Secondly, it has been our desire to profit by our mistakes, and to avoid preventable errors in the future, by determining the cause of failure to diagnosticate, as shown at autopsy.

The autopsies were all performed by Dr. Herbert C. Clark, pathologist of the board of health laboratory, Samuel Darling, M. D., chief of the laboratory. We are greatly indebted to Doctor Clark for his careful and accurate work, and the help willingly granted in elucidating many obscure points in pathological findings.

Before going into detailed analysis a few preliminary remarks are necessary, for, as Cabot states in his first paper, "it is not a simple matter to collate ante mortem and post mortem matter in an intelligent way." All patients admitted to the hospital moribund, that is to say, patients dying in the first twenty-four hours after admission, are excluded from this series. The object of this is self evident, when one considers the impossibility of obtaining a history or of making a satisfactory physical, microscopic, chemical, or bacteriological examination in many of these cases. This exclusion is not as much in the favor of the clinician as may be supposed, for many fatal malaria or lobar pneumonia patients, both easily diagnosed in even the moribund state, die within a few hours after admission to the hospital. The latitude given the clinician is another point necessitating preliminary explanation.

We regret to say that the system of granting the clinician and the pathologist the privilege of giving a primary and an immediate cause of death has never been definitely adopted in this hospital. As an example of the confusion created by the method of giving a single pathological entity as a cause of death, we might cite a case of pernicious malaria fever, complicated, as such severe infections always are, by acute toxic or degenerative nephritis. The patient lives long enough to have his circulating blood and organs cleared of the infecting parasites by the specific quinine treatment. Nevertheless, he dies in four or five days of acute degenerative nephritis and suppression of urine, because his kidneys were unable to take care of the malarial toxines contained in the destroyed plasmodia. In this case the clinician may give estivoautumnal malaria as the cause of death, while the pathologist's report may read acute degenerative nephritis or acute infection of undetermined origin. Another bad feature resulting, when the pathologist is held to give only either a primary or an immediate cause of death, is the habit formed by the clinician to include all complications of the primary disease in his diagnosis, so as to find confirmation with the pathologist. This "gunshot" method is as objectionable in diagnosis as in prescribing, and leads to similar errors.

A very good system of diagnosis is the one advocated by Dr. Henry B. Baker, former secretary of the Michigan board of health, and adopted by this board. Doctor Baker gives the primary cause of death, the immediate cause of death, and the contributing factors in both clinical and pathological
diagnoses. A recent case of ours serves as a good example. An aortic aneurysm developed in a patient afflicted with tertiary syphilis. This aneurysm, by compression and erosion, causes an empyema of the pleural cavity. Rupture of the aneurysm results in sudden death. The diagnosis here would read: syphilis as the primary cause of death, hemorrhage from rupture of aortic aneurysm as the immediate cause of death, and empyema of the pleural cavity as a contributory factor. In so diagnosticating, a correct conception can be formed as to the role syphilis plays as a cause of death. Under our system it is often impossible to do this. It would be interesting to search the mortality statistics of our large cities, and to know the small number of deaths for which a widespread and often malignant disease like syphilis is held responsible.

In the diagnosis of the nephritides, the clinician, and also occasionally the pathologist, is sorely beset. We have experienced the truth of Cabot's statement when he sums up, saying, "Aside from the immediate results of acute infections (such as scarlet fever, diptheria, tonsillitis, and pneumonia) 'acute' nephritis usually turns out to be 'chronic.' To this group of infections we may add the acute toxic nephritis of pernicious malaria. The term acute nephritis in these cases we take to be synonymous with the pathologist's acute degenerative nephritis or cloudy swelling of the kidneys. Attempts to subdivide either the acute or chronic nephritides clinically have been so unsuccessful with us that they have been given up to a great extent. In the presented series the differentiation of "acute" and "chronic" has been the only one required for a correct diagnosis. It is true that chronic nephritis can often be subdivided into the chronic diffuse and chronic interstitial types, but in determining the cause of death these niceties of diagnosis are of little value. An acute toxic nephritis, superimposed by an intermittent affection like lobar pneumonia, so completely hides the underlying chronic diffuse or interstitial condition, that the latter often becomes a mere guess.

Organic disease of the heart, excluding aneurysm, is a diagnostic term which we have been permitted to use, and which we think entirely too liberal, and too broad in its meaning. A simple dilatation of a chronically hypertrophied heart in a chronic nephritic with arteriosclerosis, is quite another condition of affairs from acute vegetative endocarditis, and each should be diagnosticated as such. In this series of cases we have accepted the term organic heart disease as sufficient. Any case diagnosticated tuberculosis as the cause of death is deemed correct, even if the localization and extent of the infection have not been determined. Under this agreement, a case diagnosticated pulmonary tuberculosis, in which the pathologist finds an acute disseminated infection with the bacillus of tuberculosis, is accepted as correctly diagnosticated.

Considering the great benefit we have derived from the commendable system in the Canal Zone, of performing an autopsy on the great majority of patients dying in this hospital, a plea for more frequent post mortem examinations in our large hospitals in the United States may not be amiss here. If the general public would once grasp the fact that, everything else being equal, the community that allows and advocates the most thorough post mortem examinations will have the most competent and trustworthy physicians, and religious prejudice and superstition would fade away more rapidly than at present. Furthermore, imported and so called sporadic cases of much to be feared epidemic diseases, in which the patients die before a clinical diagnosis is possible, are detected, and proper precautions observed to prevent serious loss in life and property. An imported case of septiceoma tuberculosis demonstrated the value of autopsies to us in this direction, very forcibly, several years ago. A careless or incompetent physician fears the autopsy as much as some of the deceased patient's sentimental relatives. So long as autopsies are as common in European hospitals as they are rare in many American, so long will Europe excel in diagnosis, the key to successful treatment.

In our total series there are 448 males, forty-five females, and seven infants whose sex has been omitted in the records. As to the age, we have 470 adults, one boy of six years, and twenty-nine infants. Of the total 500 cases, 450 are in tropical negroes, mostly from the West Indies (particularly from Jamaica and the Barbadoes), forty-six white European laborers (Spaniards, Italians, and Greeks), two white Americans from the United States, one Chinaman, and one Hindoo.

**Mortality Causes.**

The entire 500 cases of this series have been divided into the following groups, according to the cause of death as given by the pathologist:

Group I comprises in order of case frequency: Lobar pneumonia, 102; pulmonary tuberculosis, forty-six; pulmonary gangrene, six; bronchopneumonia, five; pulmonary abscess, pleurisy, and unqualified pneumonia, each one.

Group II. Disseminated and miliary tuberculosis, seventy-four; estivoautumnal malaria, twenty-one; purulent infections and pyemia (excluding those due to pneumococcus and gonococcus), twelve; malarial hemoglobinuric fever, eleven; typhoid fever, ten; pneumococcic pyemia, six; measles, diptheria, and erysipelas, each two; gonococcic pyemia, one.

Group III. Chronic nephritis (all types), forty-eight; pyelonephritis, five; acute nephritis, four; urinary calculi and hydronephrosis, each one.

Group IV. Clinical dysentery (i. e. dysentery of unknown etiology), fourteen; diarrhea and enteritis (under two years of age), nine; anemic dysentery, eight; malnutrition and congenital debility, five;
tuberculous peritonitis, three; duodenal ulcer and septic peritonitis, each two; bacillary dysentery and gastric ulcer, each one.

Group V. Organic heart disease (syphilitic aortic endocarditis, eleven; hypertrophy and dilatation due to chronic nephritis, nine; vegetative aortic and mitral endocarditis, two), twenty-two; anemia (unqualified), three; embolism and thrombosis, two; pneumococcic pericarditis, two; aneurysm, arteriosclerosis, and phlebitis, each one.

Group VI. Pneumococcic meningitis, five; cerebral hemorrhage, five; cerebral softening, simple meningitis, and alcoholism, each two; cerebral abscess, encephalitis, and tuberculous meningitis, each one.

Group VII. Acute undetermined infection, eight; ill defined disease, five; cause of death questionable (from clinical standpoint), four.

Group VIII. Epithelioma of esophagus, two; sarcomatosis, five; carcinoma of stomach and liver, three; carcinoma of rectum, carcinomatosis, and cerebellar tumor, each one.

Group IX. Atrophic hepatic cirrhosis, two; hepatic abscess (amebic), eight; acute hepatitis, one.

Group X. Chronic pancreatitis, one.

In analyzing the clinical diagnoses as sustained or refuted by the autopsy findings, we arrive at the following results:

Cause of death correctly determined. $407 = 81.40$ per cent.

Cause of death partially or incorrectly stated. $26 = 15.20$ per cent.

Cause of death questionable or undetermined. $17 = 3.40$ per cent.

Incorrect and Partially Correct Diagnoses.

Group I. Pulmonary and Pleural (6.17 per cent. failures).

Case No. found at autopsy. Condition Mistaken for, or clinically obscured by.

1 Bronchopneumonia Disseminated tuberculosis
2 Bronchopneumonia Lobar pneumonia
3 Bronchopneumonia Undiagnosed
4 Lobar pneumonia Acute undetermined infection
5 Lobar pneumonia Serofibrinous pleurisy
6 Pneumonia (unqualified) Undiagnosed
7 Pulmonary gangrene Chronic nephritis
8 Pulmonary gangrene Lobar pneumonia
9 Pulmonary abscess Bulbar palsy
10 Pulmonary tuberculosis Pneumonia (unqualified)

Cases one and two of this group were pardonable errors. Case one presented an unusual complication which distorted the picture and findings of bronchopneumonia. A spontaneously healing amebic liver abscess had caused red atrophy of the liver, blocking the hepatic circulation and causing a hydroperitoneum. This, added to the pulmonary signs, with a low leucocyte count, a uniformly enlarged liver, and a serofibrinous pleuritis, completed the usual picture of a terminally disseminated tuberculosis. Case two was a massive bronchopneumonia in an infant—almost impossible to differentiate from a lobar pneumonia. In case three, a fifteen day old infant, it would seem as though inadequate physical examination was at least partly to blame for the failure in diagnosis. The pulmonary findings, on admission, were very conveniently recorded with a question mark, and no further examinations made (at least not entered on the chart) for the following three days, at the end of which death occurred. Case four is an excellent example of the common error to neglect repeated physical examinations on a patient with a definite diagnosis. The patient was a measles case in which lobar pneumonia developed as a complication, and of this he died on the eleventh day after admission. The error in case five is a very pardonable one. The patient’s lobar pneumonia was masked by a quite extensive serofibrinous pleurisy. Death occurred thirty-six hours after admission. Lack of systematically repeated physical examinations is again to blame for case six not having been diagnosed as bronchopneumonia at least. Repeated physical examinations were made, but they all seem to have been confined to the gastrointestinal tract, as the infant was evidently suffering with a complicating diarrhea. The diagnosis in case seven is the result of pure negligence and inexperience on part of the ward physician. While it is true that the chronic nephritis was present to a degree, as diagnosed, the septic temperature chart, not to mention the undoubtedly evident gangrenous odor of the sputum, should have pointed to other pathological processes, in addition, and should have suggested another physical examination. The ward nurse’s notes as to cough and expectoration are also conspicuous by their absence. Case eight, also a missed gangrene of the lung, may be excusable. Death took place early in the course of a severe lobar pneumonia, which masked the rapidly developing gangrene. Case nine was a very interesting one of bulbar palsy. The abscess, due to aspiration, following respiratory palsy, was located more or less centrally over the diaphragm. The paralysis of the respiratory muscles made a satisfactory physical examination of the chest quite difficult. The last case of this group was a miliary pulmonary tuberculosis patient who died on the fifth day. The diagnosis came as near being correct as it possibly could, without actually being so. The sputum examinations were negative.

Four of these ten cases might have been diagnosed, had more attention been given to repeated, thorough physical examinations. In none of the ten cases did the failure to diagnostic time injure the patient’s chance of recovery appreciably.

Group II. General Infections (9.93 per cent. failures).

Case No. found at autopsy. Condition Mistaken for, or clinically obscured by.

1 Disseminated tuberculosis Atrophic hepatic cirrhosis
2 Disseminated tuberculosis Exhaustive infection psychosis
3 Disseminated tuberculosis Meningitis
4 Disseminated tuberculosis Meningitis
5 Acute miliary tuberculosis Malnutrition, bronchopneumonia
6 Acute miliary tuberculosis Septicemia
7 Pneumococcic septicepyemia Serofibrinous pleurisy, tuberculosis meningitis
8 Pneumococcic septicepyemia Meningitis
9 Typhoid fever Septicemia
10 Typhoid fever Intestinal hemorrhage, malaria
11 Typhoid fever Undiagnosed
12 Pyemia Acute ileocolitis
13 Pyemia Malaria
14 Pyemia, Hepatic abscess, general tuberculosis
The first six cases of this group show the difficulty often encountered in diagnosing a generalized tubercle bacillus infection. Case one was admitted with a frank lobar pneumonia which ended by lysis on the fourteenth day. Many weeks of normal temperature followed, but an ascites developed and the patient was tapped repeatedly. A clear serous fluid of low specific gravity was obtained. On percussion, a small liver was easily outlined. Nevertheless, the patient died of disseminated tuberculosis. Although at autopsy the lungs showed only a few miliary tubercles, the spleen, liver, and peritoneum were completely studded with them. Case two gave cerebrospinal symptoms on admission, and patient became delirious. Brain and cord syphilis was suspected, though the Wassermann test, made with the serum of the peripheral blood, was negative. The last week the patient was in coma, with a normal or subnormal temperature. At autopsy the original focus of the disease was found to be an old vertebral caries, not to be demonstrated clinically. In case three a good attempt was made to ascertain the etiology of the existing meningitis by performing several lumbar punctures, culturing the cerebrospinal fluid and examining it for tubercle bacilli. As frequently happens, the result was negative, and a definite diagnosis not reached. Case four is very similar, except that a blood culture was substituted for the second cerebrospinal fluid examination, because of the high absolute and differential white blood count. An excuse for the error in case five will be granted by all. Here the spinal fluid was negative for tubercle bacilli ante mortem, but positive post mortem. The error in case six will be as readily understood as in case five. Here again the spinal fluid was negative for tubercle bacilli, though the meninges were affected. It is probable that prolonged search (for which our time is usually too limited) in spinal fluid stains would in some of these cases have decided the diagnosis. Generally speaking, these cases tend to show that, given an acute infection with a low leucocyte count, a negative blood culture early in the disease, signs of meningitis with a negative bacteriological result in spinal fluid examinations mean tuberculosis. Case seven proves the proverbial exception to this rule. This case was admitted with serofibrinous pleurisy and acute meningitis. Blood culture and spinal fluid being negative, and, in addition, the presence of a low leucocyte count, the diagnosis of tuberculous pleurisy with extension to the meninges seemed a fair conclusion. A resolving lobar pneumonia was found at autopsy, masked by the pleural effusion and complicated by a pneumococcal septicemia. The pneumococcal meningitis found in case eight, would have been diagnosed as such if the examination report of the spinal fluid sent to the laboratory had reached the ward before the death of the patient. Here lack of time caused a diagnosis to be given which per se is only a symptom. Cases nine, ten, and eleven are typhoid fever cases in which the patients died on the fourth day after admission. In two, the blood culture was obtained too late for the ward to receive the positive return before death. One of the cases in which the patient died of intestinal hemorrhage was complicated by estivoautumnal malaria. In the third case the blood culture was negative. Case twelve was an infant suffering with ileocolitis. There seems to have been a systemic infection from the intestines, which was of course easily missed in the presence of the focal symptoms. The next case, a pyemic death on the second day (probably entry to be found in an ulcerated colon), is an excellent example of the fallacy to diagnose malaria per se, as a cause of death, when a properly made Romanovsky stain of the peripheral blood fails to show the asexual plasmodia. In our experience in the tropics we recall no fatal case of malaria in which the ordinary peripheral blood film, stained with Hasting's stain, did not show the infecting organism without much expenditure of time and patience, provided that the patient died directly of the infection, and had not been given large doses of quinine prior to examination. The last case of this group is a partially diagnosed one. The hepatic abscess (or rather abscesses) was part of the pyemic process, while the general tuberculosis, also diagnosed, was an error of commission.

Excepting the criticism concerning malaria in case thirteen, this group of cases was well handled. The cases were conscientiously examined, considering the time at the disposal of the physicians. It is doubtful whether further or more complete examinations during the time under observation would have been conducive to making a better diagnosis. None of these patients would have gained anything, had a correct diagnosis been made.

**Group III. Renal (1695 per cent, failures).**

</tbody>
</table>

The only case of acute nephritis, heading this group, was an interesting one. The patient, a Hindoo, was admitted suffering with a severe anemia, suppression of urine, and persistent vomiting. The blood picture was that of a secondary anemia. A clear cut history of a recent malarial attack, voiding of "dark" urine, and the presence of an enlarged spleen and liver, brought about the diagnosis of posthemoglobinuric fever with suppression. Autopsy on the fifth day showed extensive malarial pigmentation of the spleen and liver, with an acute nephritis, but hemoglobin casts were not present. In the light of autopsy findings, the case seems to have been an acute degenerative nephritis, following a recent acute attack of
malarial fever. The diagnosis of hemoglobinuric fever evidently overshot the mark, but cannot be considered entirely unjustifiable. Case two presents rather a humiliating error of commission. The chronic nephritis, of which the patient died, was recognized without difficulty. A bronchopneumonia diagnosticated clinically was also found. In attempting to rule out the possibility of the pulmonary infection being tuberculous, sputum specimens were examined. Unfortunately, a mistake occurred by which a positive tuberculous sputum of another patient was sent to the laboratory as having been obtained from this patient. The diagnosis of tuberculosis was the result. This mistake taught us the lesson never to diagnosticate a case of pulmonary tuberculosis from the sputum until the bacillus has been found in two independently obtained specimens. Case three shows an easily made error. A chronic diffuse nephritis with severe pulmonary congestion was interpreted as bronchopneumonia and acute nephritis. A little more attention paid to repeated urinary analyses in case four might have shown that, while the diagnosticated atroic hepatic cirrhosis was present, the kidneys were also at fault. Possibly this case belongs to the group of questionable ones, as both liver and kidney function seems to have been severely impaired. Case five demonstrates the uncertainty of central nervous system diagnosis. The chronic nephritis was easily recognized, but an error of commission was made by interpreting a hemiplegia, caused by terminal central edema, as a hemorrhage. This throws the case into the class of partial diagnoses. Similar errors are not uncommon and are easily made. Cases six to ten are examples of rather frequent, yet often neglected, pathological conditions. The greater interest taken in this hospital of late in urine cultures, cystoscopy, and ureteral catheterization, we hope, will prevent errors or absence of diagnosis in many of these cases. The clinical diagnosis in case ten, considering that cystoscopic examination was not available, is certainly commendable. The cases diagnosticated cystitis, clinically, teach the old lesson that infections of the bladder should always be looked upon with suspicion, as they are generally the result of disease above or below in the genitourinary system. The importance of diagnosticating and treating these infections early and thoroughly is being generally recognized. It will not be long before all large hospitals have added a urological division to their special departments.

Excluding cases one, three, and five, this group could have been much improved on, as already shown. In cases six, seven, eight, and ten a correct diagnosis, followed by surgical intervention, might have saved some or all of these four patients, provided that they had applied earlier in the disease.

### Group IV. Gastrointestinal (24.44 per cent. failures).

</tbody>
</table>

Case one of this group needs little comment. It demonstrates the difficulty of visceral ulcer diagnosis, especially in the colored race. The sensitivity of the negro's peritoneum seems to be much less than that of the Caucasian. The former seldom complains of any abdominal pain until the ulcer has perforated. Even then, a generalized acute peritonitis is often only spoken of as a "cutting in the bowels." In this case the patient died suddenly while convalescing from a malarial attack. The shock of perforation seems to have been the immediate cause of death. The unusually severe attacks of abdominal colic, in a negro plumber and lead fitter, were the reasons why duodenal ulcer was not seriously considered in case two. Granting the presence of lead poisoning, which seems to have been very doubtful in this instance, a correct diagnosis of the complicating ulcer would seem exceedingly difficult. Had the perforation in case three not occurred so soon after admission, an analysis of the stomach contents might have helped materially in correcting the tentative diagnosis. In all three cases the patients died within a few hours after perforation. In cases four and five the term clinical dysentery is employed as a cause of death. By this term is meant an ulcerative colitis, or enterocolitis, of which the etiological factor cannot be demonstrated. The dysentery in case four was probably a secondary ulcerative enterocolitis, a frequent termination of chronic interstitial nephritis with us in the tropics. Chronic nephritis was found at autopsy as clinically diagnosticated. The failure to recognize the dysentery before death was due to a laxity in macroscopical and microscopical stool examinations by the ward physician. Only negligence can account for the fact that a patient whose chart shows from fourteen to eighteen bowel movements each day was not examined for dysentery. The same may be said of case five, with the addition that the nurse seems to be incriminated, for her records show constipation—a quite unusual condition of affairs in an infant dying with dys-entery. Case six belongs to the group of partially diagnosticated cases, for the clinical dysentery which the pathologist gives as the cause of death was fairly well diagnosticated clinically as chronic ulcerative colitis. It is difficult to state whether the clinician was simply guilty of an error of omission, when he diagnosticated the extensive caries of the nasal bones, tertiary syphilis, or whether he mistook leprosy for syphilis. The result of this failure has been that all caries of the bones, diagnosticated as syphilitic, are now examined routinely for lepra bacilli. In case seven the stools were examined on several occasions, but negligence seems to have been present, in that fresh specimens were not utilized. The diagnostician who relies on cold stool examinations in dysenteries will seldom recognize an amebic case. The incorrect diagnosis of acute tuberculosis was a guess—a post mortem one—on part of the physician, and deserves neither the name diagnosis nor any further
comment. The criticism concerning fresh stool examinations in case seven explains case eight also. The failure to diagnosticate case nine correctly was undoubtedly due to the shortness of time under observation, thirty-six hours. Focal congestion of both lungs was taken to be bronchopneumonia. The mistake in case ten is an easily comprehended one in an infant of eight months. Whether or not the diagnostician deserves censure here can hardly be determined from the chart at hand. The last case of this group is still another instance of being satisfied with a primary diagnosis and neglecting further examinations. The patient had chronic diffuse nephritis, as correctly diagnosticated, but the well developed tuberculous pleurisy and peritonitis might have been recognized if looked for.

Four of these eleven cases might have been diagnosticated if the stool examinations had been received proper consideration. The great value of microscopical examinations of the feces does not seem to be sufficiently recognized by many physicians. In another case, a simple carbolfuchsin and Gabbet's stain would have shown the bacillus of leprosy by the millions, and would have made the diagnosis. One failure was due to inadequate physical examination. As far as the patient's outlook is concerned, it is problematical how much either medical or surgical treatment would have accomplished in the ulcer cases, had they been diagnosticated as such. In cases seven and eight it is our opinion that the bismuth treatment for amebic dysentery might have changed the final outcome in favor of the patient, had the infecting entameba been found in the stool.

</table>

The first patient of this group was admitted in very poor condition. An acute hemorrhagic pleuritis, bilateral, obscured the pericardial involvement. Though weakness of the cardiac sounds was noted, it was ascribed to the acute myocarditis of sepsis, a not uncommon mistake. Cases two to five are examples of the extreme difficulty of clinically diagnosti-cating myocarditis. In case two the reverse mistake found in case one was made, the distant, weak cardiac sounds, and the arrhythmia of cardiac action being taken to indicate adhesive pericarditis. In case three the patient died after a pulmonary hemorrhage induced by passive congestion of the lungs, incidental to myocardial weakness. Pulmonary tuberculosis was diagnosticated simply because of the fatal hemorrhage, in spite of several negative examinations of the sputum for tubercle bacili. It was quite impossible to diagnosticate the myocardial condition in case four because of a masking serofibrinous pleurisy clinically recognized. Here, also, pulmonary tuberculosis was diagnosticated, notwithstanding the negative sputum, because of the presence of a chronic serous membrane inflammation and pulmonary congestion. The fifth patient was admitted to the ward with ascites. After the emptying of the peritoneal cavity, the edge of the lower border of the liver was charted as hard and nodular. The conception of neoplasm, causing hepatic cirrhosis, seems to have been uppermost in the clinician's mind. Death occurred suddenly. At the autopsy chronic myocarditis and marked cardiac dilatation were found. A moderate cirrhosis of the liver, and an associated cholelithiasis, coupled with the difficulty of diagnosti-cating myocarditis and acute cardiac dilatation, seem to have been the clinician's downfall. In the sixth case of this group the presence of bronchopneumonia, pericarditis, and pleuritis, completely hid the vegetative endocarditis which the pathologist gave as the cause of death. The clinical diagnosis made was, of course, not incorrect in itself, but rather too general to be accepted. It may be added that an ante mortem blood culture remained sterile. The concluding four cases of this group are more or less partially correct diagnoses. In case seven gastric carcinoma constitutes an error of commission that should not have been made, because the sole reason for the diagnosis rested on the presence of severe anemia, emaciation, and vomiting, in an old man. The patient died before clinical analysis of the stomach contents was made. In case eight the primary disease, syphilis, had been recognized. The site of chief destruction was also known, but the actual aneurysm was not found. How much the diagnosti-cating physician is to be held responsible for this error can, of course, not be said from clinical records alone. In case nine the cause and the effect of the embolism, which was located in the lung, were self evident. The error consists in the mistaken opinion, expressed by the physician in his daily notes, that he considered the pulmonary hemorrage tuberculous in origin. In the last case, case ten, the very common mistake is made of ascribing the hemiplegia of embolism to cerebral hemorrage. In the presence of the recognized heart lesion, embolism should probably have been given the preference.

All the cases of this group were difficult ones, and in none of them could additional aid have been rendered the patient, had the diagnosis been correctly made.

GROUP VI. CEREBRAL SYMPTOMS (47.36 per cent. failures).

CARSTENS: NERVOUS CONDITIONS AND PELVIC DISEASES.

By J. H. Carstens, M. D.,
Detroit, Mich.

When a woman has attacks of headache it is assumed by the laity, and often by the profession, that she must have some diseased condition of her pelvic organs. She goes to a physician, and he finds from the history of the case that she has had a number of children, the youngest one perhaps ten years ago, and that some two or three years ago she began to have attacks of cephalalgia with every menstrual period, just before, during, or after. Then, continuing that way for a year, every month the attacks became more frequent, and now she has attacks at irregular times, one or two a week, or one in two weeks. On examination he finds a badly lacerated cervix, and proposing an operation, performs it and the woman is cured. He bases his diagnosis on the fact that this condition occurred at first only during the menstrual period, and that thereafter the pelvic congestion and irritation must have had something to do with the pain in the head. Also that in the course of time the condition became aggravated, and the attacks more frequent.

Now, some of you may say, "Why, this woman had a lacerated cervix for at least six or seven years, and never had any attacks. What was the cause of the attacks; why did she not have them immediately?" This seems very plausible, but is not true, for a woman who has prime health may have some pelvic trouble, and no nervous manifestations; but let her get an attack of typhoid fever, cholera morbus, indigestion, or have some worry and anxiety, in fact anything that lowers her state of health, and then the nervous condition will manifest itself. At the same time, I think that in some cases the contraction of the cicatrix may in the course of time become so great as to compress the nerve filaments, and that symptoms are produced which in the earlier stages of the scar were not present. This patient was cured by the proper diagnosis and the proper repair of the tear.

Another patient comes along, with almost the same symptoms and history. She also has a tear, the doctor makes the diagnosis and operates upon her, but she is not cured; she is just as bad as ever. She finally goes to another physician, who is a diagnostician; he finds some little variations in the symptoms that make him suspicious, and sends her to an oculist for careful examination. The latter finds astigmatism, myopia, or something else, fits

*Read before the Buffalo Academy of Medicine, December 17, 1912.*
her with proper glasses, and, lo and behold, the woman is cured. The operation did no good; in fact, was not necessary.

Another patient comes along; she also has the same attacks, same history, same condition. Attacks seem to be worse at night, she is unable to sleep until early in the morning. She has a lacerated cervix, and is also operated upon, but remains as troubled as she was before. Then she also goes to a diagnostician. He looks her over carefully, finds that it is an obscure case of syphilis, puts her on mercury, and relieves her in a short time. Another woman comes along with the same kind of history, the same pelvic condition with attacks of headaches, nervousness, palpitation of the heart. Better for a week or two, then worse again. She is also operated upon, and promises are made that all her nervous symptoms will disappear. But they do not—in fact she is gradually getting worse. She goes to a diagnostician, and he makes the diagnosis of exophthalmoic goitre. If the first physician had studied up on the ductless glands, and been up to date, he would not have made the mistake. I think that this particular kind of mistake is often made. Still another one comes along with the same train of symptoms, same diagnosis. She is not relieved by operation, she gets discouraged, gets some patent medicine, and feels better, but is not cured. So finally she goes to an up to date medical man, who can make a diagnosis, and who on thorough investigation finds that the woman is suffering from auto-intoxication. She has constipation, she eats too much nitrogenous food, or too much candy; the whole fluid intake in twenty-four hours is a pint and a half. Her liver is dry, her kidneys do not act; she suffers from reabsorption of effete matter. The doctor regulates her mode of living, and cures her. The operation was of no benefit and unnecessary.

And so I could continue upon this one nervous symptom of headache for the whole time allotted to me. Instead of previously saying lacerated cervix. I might just as well have said lacerated perineum, retroverted uterus, tuboovarian inflammation, disorders of menstruation, or any other abnormal pelvic condition. Instead of saying headache, I might have said backache, epilepsy, hysteria, or any other nervous condition, including psychoneurosis.

Now, let us take up some other morbid condition. The woman has a displaced uterus, and has attacks of the kind mentioned or some other nervous symptoms. By keeping the womb in place with a supporter or by operation she is relieved. The woman may be thirty years old, and may never have had any symptoms before. The woman is thirty, yet received that displacement, as the result of falling off a bicycle or a swing, twelve years before. She had no symptoms because she was in good physical condition, but two years ago, something was added, perhaps a fall, severe lifting, or some disease. The next woman with a displaced uterus is not cured with a supporter or operation, the wrong diagnosis has been made, and perhaps an unnecessary operation performed. Another patient comes along who is complaining of distress in the right side, with symptoms of indigestion, bloating, distress after eating, or perhaps relieved by eating; she is irritable and cross, and generally out of sorts. She has been losing flesh. An examination is made, and while the pelvic organs are found to be normal, it is discovered that she has a loose kidney. The doctor decides to operate, and fixes the kidney (if he knows how), but the patient is no better. She has been promised complete relief, but does not get it. She goes to another surgeon, who makes a diagnosis of duodenal ulcer, or perhaps trouble with the gallbladder. He operates upon her, and relieves her. The loose kidney had nothing to do with her condition, although in some cases prolapsed kidney is an important etiological factor. These are the most puzzling cases to make a diagnosis, when two or three different conditions exist. Which one is causing the trouble, one or all together?

A woman, thirty years old, mother of four children, had some inflammation on the right side immediately after the birth of the last child. This is accompanied by fever, but the symptoms are not serious, and in the course of two or three weeks she recovers, by being treated on general principles. In the course of eight or ten months she again has a pain in the right inguinal region, appearing during the menstrual period. The doctor makes a diagnosis of pus tube, as he has the history of pyogenic infection. However, the attack is not serious and subsides, but recurs at the next period. The woman also has indigestion and is run down, and the doctor finally urges an operation, to which the patient consents. The right tube and ovary are removed, but the patient is not improved. The attacks recur later at irregular intervals, and the patient consults a diagnostician, who makes the diagnosis of chronic catarrhal appendicitis, and with great difficulty persuades the woman to have another operation. She recovers, and is entirely cured. The appendix was found to be club shaped, kinked, and stricteed, and contained several enteroliths. The symptoms of pain, being well down in the pelvis, and not at McBurney's point, deceived the first physician.

One of the nervous symptoms women often complain of is backache, and backache, while generally attributed to kidney trouble in men, is commonly supposed to be due to pelvic trouble in women. A patient with headache goes to a physician, who is superficial, and he may find a retroversion of the uterus, and proceeds to perform one of the numerous operations recommended for that kind of displacement. The operation was a success, but the patient is not relieved, because the backache was due to an entirely different condition. If we take hysteria, how often do we find pain on the left side above Poupart's ligaments, and how many left ovaries have been removed uselessly to relieve this nervous symptom of hysteria. If we take up the question of the more serious conditions, for instance epilepsy—which often manifests itself at first only at the menstrual period, at the beginning of puberty, but the attacks of which, in the course of time, comes on at frequent intervals—we find that such patients are often brought to a gynecologist, to remove the ovaries for the purpose of curing the epilepsy. As a rule, the result will be sadly disappointing. However,
these patients are often erotic and feeble minded. Sometimes they become pregnant, and if we believe in eugenics and think it is a good thing to stop the breeding of such people, we do a good work for the race in removing the ovaries; but we must not be too sure of curing the epilepsy. I have seen a few cases cured, but more often this was not the case.

When it comes to the still more serious condition of insanity, we must be especially on our guard. I have seen a few patients on the verge of insanity who were absolutely cured by some pelvic operations, but I have also had lamentable failures. I remember operating in one case on a woman, near the menopause, who had been in an asylum. She was worse during menstruation. I performed a vaginal hysterectomy, including the ovaries, and she seemed very quiet and rational; but forty-eight hours afterward jumped out of the second story window of the hospital. She was returned to bed and thereafter restrained, and finally sent home, but she is to-day at the asylum in Mainstee. Years ago a young woman was brought to me suffering from menstrual insanity for three days every month. During one of these spells she attempted to shoot the young man to whom she was engaged. It was apparently a plain case of menstruation insanity. "Ergo," I thought, "stop menstruation and you cure the insanity." I stopped the menstrual period all right, but she is now in an insane asylum in Ohio. This kind of case makes us suspicious, and very careful in operating.

Professor Bossi, of Genoa, lately reported in the Zentralblatt für Gynäkologie some cases of septic endometritis causing insanity. Some of these patients were in the asylum for a considerable time and most violent, even maniacal. He had them transferred to his clinic, and cured them by dilatation, currettage, and drainage. The results were remarkable, the patients being restored to perfect health. Some of them were married, and the trouble of a puerperal origin; others were virgins. Such cases must certainly be rare. In these cases of insanity due to pelvic troubles I have always held that an insane woman should be relieved of all her troubles, if possible, and if she had any pelvic diseases (tumors, abscesses, etc.), they should be cured just the same as affections of the kidneys, lungs, or stomach. But I do not believe that many cases of insanity are caused by pelvic troubles, although I have always believed that puerperal insanity is puerperal infection in ninety per cent. of the cases, and always treat it as such. As to infection, it is to me marvelous how a slight sepsis, like a stitch abscess, affects some persons: they are perfectly wild, abusive, and delirious, but when the septic condition is relieved all their nervous symptoms disappear. I have often had them apologize to me for being so unreasonable, and say they could not help it. In the early stages patients with psychoneurosis very often think that the trouble is due to some pelvic disease. They may have symptoms indicating this, and, in fact, may have it and, by continually thinking about this trouble in the pelvis, it grows on them; they magnify it, and their mental condition is undoubtedly made worse. If in such patients we cure their pelvic diseases, they are often improved in mind, and it seems to me that in many cases in the earlier stages they can be absolutely cured of the mental trouble by relieving them of the pelvic pathological condition. Of course, not all of them have the same happy outcome; some of them branch off on some other condition of their system, stomach, throat, nose, etc. Nevertheless, much relief is given—they are improved, and often the neurologist can afterward cure them, which he could not do if the gynecologist had not first relieved them of their pelvic diseases.

As from statistics collected in large institutions only from ten to twenty-five per cent. of the women have pelvic diseases that can be recognized, it is self evident that not many cases of mental diseases can be due to reflect pelvic troubles. In Prussia there are 127,000 insane in hospitals (men, 71,000; women, 56,000), hence pelvic trouble cannot cause many cases of insanity. A neurologist calls me in consultation to see an unmarried woman, twenty-four years old, who has some symptoms, which make him think that perhaps she has some pelvic trouble. I examine her, but find nothing abnormal. During the digital examination I notice a spasmodic contraction of the vagina, and know that if I had continued the examination she would have had an orgasm. On inquiry as to what I found. I told the neurologist that the girl was suffering from ungratified sexual desires, and that I really believed she did not know what sexual intercourse was. Then he answered, "I see it all now; I did not think of that; it is all plain to me now." This poor girl should be married and have children—that will cure her. A married lady, thirty-nine years old, came from an interior town to consult me. She said she was nervous, irritable, cross, etc., and she had been married fifteen years, but never experienced sexual orgasm, though she had sexual passion. Thus, she was never satisfied. Poor, mistreated woman, what could I do? I knew of no remedy that would help her. This kind of trouble is frequently the cause of our numerous divorce suits.

That the sexual functions are often at the bottom of the nervous condition we all know. A woman comes to consult us who has been married ten years but has only one child, nine years old. If we examine her and find absolutely no trouble we naturally ask ourselves, Why does she not have more children? We must get at the bottom of the trouble, and on inquiry are told that she does not want any more. Again we ask ourselves, How does she accomplish it? Naturally, on inquiry, we receive different answers from such patients as to how they prevent pregnancy. Very, very rarely they will say they have no connection. Some use injections of different solutions or icy cold water, and these produce disturbances. Some practice curitus interruptus, which injures the woman more than the man. This vicious practice, continued for months and years, finally produces a nervous condition, with various obscure symptoms, which cannot be definitely labeled unless one is a skilled diagnostician and goes to the root of the trouble. What a wonderful change you produce in such women in three months if you make them estab-
lish normal sexual relations. But I see them raise their hands in horror. "You must not talk of that; that is tabooed; it is nasty," they say. Now I hold that it is nothing of the kind. The sexual act of a married couple is a perfectly clean and noble act; the act is only nasty when promiscuously performed, or done in a perverted manner. The profession has neglected this subject and must teach the laity correct views on the question, and by instructing people many misunderstandings in families can be prevented and divorces avoided.

I have called attention to movable kidneys, because a movable kidney is virtually only found in women, and therefore I might say it belongs to the department of the gynecology. I noticed that Billington reports remarkable results in the fixation of loose kidneys for insanity, and I have no doubt that sometimes it does wonders, like everything else; but I cannot believe that a loose kidney is the cause of many cases of insanity. In conclusion I would say that the various nervous symptoms found in women are not always due to pelvic trouble, but not infrequently to many other circumstances, such as mode of living, diet, occupation, zymotic diseases, etc. If pelvic trouble is found it is sometimes very difficult to make a correct diagnosis, as the pelvic condition may not be at the bottom of the nervous trouble. This is all the more difficult if we find two or three different pelvic conditions, either one of which might produce the symptoms; for instance, a tear in the uterus, with displacement of the organ, and movable kidney, with or without general abdominal ptosis. When such complications are found the prognosis should be very guarded, and all the conditions should be relieved, and then the patient may require long continued aftertreatment.

CONCLUSIONS.

1. The differential diagnosis of nervous conditions in relation to gynecology is very difficult.

2. The medical man very often gets himself in trouble by jumping to conclusions and promising too much.

3. This is especially the result in cases of surgical interference.

4. It is therefore self evident that the gynecologist must not only be a good physiologist, besides a general practitioner, but he must be especially well informed on diseases of the nervous system.

620 Woodward Avenue.

MYOPIA PREVENTION BY TEACHERS.

By W. H. Bates, M. D.

New York.

Myopia with elongation of the eyeball is incurable. It is usually acquired during school life. Acute myopia, spasm of the accommodation, or functional myopia is an early stage of incurable myopia. The cause of myopia is an effort to see distant objects.

Corroborated:

1. Myopic refraction has always been produced in man and the lower animals when regarding unfamiliar distant objects which required an effort.

2. Myopia was prevented in the public schools of Grand Forks, N. D., for eight years by methods which prevented an effort to see distant objects.

3. Myopia was always benefited by treatment suggested by the cause.

4. The cause suggested a method for the experimental production of myopia in rabbits, dogs, and cats.

5. Physicians, teachers, and others interested have investigated and confirmed these facts.

6. It should be emphasized that there is but one cause of myopia, an effort to see distant objects. There is no other cause.

Near use of the eyes is not a cause of myopia. By the aid of simultaneous retinoscopy, it was always demonstrated that an effort to see near objects lessened myopic refraction or produced hypermetropic refraction.

Prevention of diseases is usually suggested by the cause. When the cause is known, prevention may be successful; but when the cause is not known prevention is uncertain. For example: Yellow fever, twenty five years ago, was not prevented by quarantine, disinfection, or other methods until the cause was discovered, the infected mosquito. By removing the cause, yellow fever has been eliminated from Havana and Panama.

Likewise, previous efforts to prevent myopia have failed because the cause was not known. It was erroneously believed that when school children regarded, or made an effort to see, distant objects, that the eyes were at rest or that accommodation or myopic refraction did not occur. Simultaneous retinoscopy disproved this assumption. It has been repeatedly demonstrated with the aid of the retinoscope that all school children with normal eyes when regarding unfamiliar writing or figures on the blackboard, distant maps, diagrams, or pictures had myopic refraction. It was quite otherwise when they regarded a familiar distant object. The retinoscope used at the same time indicated no myopic refraction.

The Snellen test card, while being of use for testing the acuity of vision, was found also during the past ten years to be the best distant object for exercises in distant vision. It should be memorized and thus made a familiar distant object. After its daily use for half a minute or longer myopia was prevented; and, in addition the vision of many pupils with defective sight was improved for an unfamiliar Snellen card. For writing and figures on the blackboard, and for other distant objects. Furthermore, near vision was benefited by the use of the Snellen card. Many pupils stated that they could study their lessons with less or no discomfort.

Myopia prevention was introduced in Public Schools Nos. 6, 183, and 186 of New York city, January, 1912; later, Public Schools Nos. 46 and 43 tested the method.

THE METHOD.

A Snellen test card was placed permanently where all the pupils could see it from their seats. Daily the teachers recommended all the children to silently read the card with each eye separately, covering the other eye with the palm of the hand in such a way as to avoid pressure on the eyeball.

Records were made with the same card or with
an unfamiliar card for testing the vision. This matter is discussed below. Each line of the Snellen card is designated by a number which indicates the feet that the line should be read by the normal eye. Records of the vision are written in the form of a fraction: The numerator of the fraction represents the distance in feet of the pupil from the card while the denominator denotes the number which designates the lowest line read. Records were usually submitted as follows:

Public School No. 6.

The first school authorized to try the method was Public School No. 6, Miss K. D. Blake, principal. In November, 1911, she permitted me to test and record the vision of 115 pupils. Later, she informed me that a medical inspector examined the same children and found my record correct.

In one class room she observed me relieve the defective vision of five pupils in fifteen minutes with the aid of the Snellen card. She was told that the teachers were able to improve the vision of all pupils in the same simple way and thus, logically, prevent myopia.

The memorized Snellen test card aroused much skepticism. Its value for testing the vision was questioned by most teachers. To settle the matter, Miss Blake had the vision of 1,500 pupils tested. January, 1912, with a memorized Snellen card by the teachers. Soon afterward, the vision of the same 1,500 pupils was tested with an unfamiliar Snellen card. The tabulated records of both tests were sent at his request to Gustave Straubenumiller, associate superintendent, with the following conclusion: "The figures submitted are interesting and it would seem as though Doctor Bates had, to a certain extent, proved his point." The test was repeated in June, 1913, and the memorized Snellen card was again found satisfactory for testing the vision. Objective tests were conclusive, and demonstrated the interesting fact that school children did not deceive themselves or others, when their vision was tested with a memorized Snellen card. When a pupil said he was reading the memorized Snellen card with normal vision, the retinoscope used at the same time, indicated no manifest error of refraction; the eye was adjusted for normal vision.

The reliability of the teachers’ records of the vision was investigated by Miss Blake. At her request the health department sent a medical inspector who also tested the vision of the pupils and told Miss Blake that the records of the teachers were reliable and correct.

One teacher taught her pupils to test and record the vision of their own eyes daily. They convinced me that they did both correctly.

The pupils learned the value of the Snellen card for improving the sight; and many obtained by their own efforts normal vision without glasses. This fact was observed also in other schools. One teacher asked me to investigate a boy who said his vision had improved from 20/200 to 20/20. I found the boy had normal vision, but I had trouble to convince the sceptical teacher that the pupil was able to see perfectly.

It is suggested that a monitor be appointed in each class to improve the vision of all pupils with defective sight.

Miss Blake deserves much credit for her intelligent methods of investigation of myopia prevention by teachers. When Dr. C. Ward Crampton, the director of physical training, investigated the method and visited her school early in 1913, he told her to remove the Snellen cards and discontinue her efforts to prevent myopia. This command was so manifestly unfair to the method at the time that she refused to comply without an order from her superiors. I cannot express in words my gratitude to her for her championship of the method. The records she submitted in June, 1913, of pupils also tested in October, 1912, were the best of all. She desires to continue the method and is now willing for me to use the ophthalmoscope to obtain more scientific facts for the benefit of school children.

Finally, when the question was asked her, "Do you believe that the Snellen card was a benefit?" she replied: "Yes, I do; but I do not understand it."

Public School No. 183.

In the Fall of 1911, Miss A. J. Farley, principal, Public School No. 183, became interested in myopia prevention and consented to try the method in her school. In the beginning most of the teachers neglected to use the method. This was true of other schools.

Miss C. V. Dillon, ungraded class, was the first New York city teacher to submit accurate records of the vision of school children before and after the use of the method of myopia prevention. She recorded the vision of all her pupils, October, 1911, and again, December, 1911. During this time the Snellen card was not used and the vision of no child improved. After the Snellen card was placed permanently in the class room, January, 1912, she gave her pupils daily exercises in distant vision with its aid. She noted a prompt improvement in the sight. The vision of the same children was recorded, March, 1912, and June, 1912, using an unfamiliar Snellen card for testing the sight. The records indicated that the vision of all was improved. She continued the use of the Snellen card, daily, during the school year, 1912-1913.

June 27, 1913, Miss Dillon was asked her opinion of the method. She answered that her results continued good, and offered her recent records as additional evidence in favor of the method. At one time during the year the health department prescribed glasses for all her pupils. As long as a child wore glasses she refrained from giving it exercises in distant vision with the memorized Snellen card, by order from the principal; but, after a child appeared in school without glasses she believed that she was privileged to benefit it with the Snel-
len card. She described in detail the results obtained. Some pupils, even with glasses, were unable to see the writing on the blackboard from their seats. In a short time their vision improved without glasses, so that they had no further difficulty with their sight. Others complained of eye pain or had trouble in seeing to read. They held their books close, about six inches from the face. The use of the distant Snellen card gave them relief and they later read without effort or discomfort at a comfortable distance, about twelve inches. She discarded glasses and relieved her own eyes by the use of the Snellen card. I believe that if all teachers were as enthusiastic or as conscientious as Miss Dillon, no child would acquire myopia while attending school.

The success of Miss Dillon with the method encouraged Miss Farley, the principal, to persuade other teachers to try it.

October, 1912, Miss Knauff, 2A, reported that the vision of six pupils with defective sight did not improve after one week when the Snellen card was not used. After the method was employed daily for one week, all had improved, and five of the six defectives obtained normal vision without glasses. Similar results were obtained by four other teachers. Miss Farley asked the health department for an investigation to determine the reliability of the teacher's records. The medical inspector sent tested the vision of the same pupils and told Miss Farley that the teachers tested and recorded the vision correctly. Relapses occurred after the use of the Snellen card was stopped.

In January, 1913, Miss Farley had the vision of all the pupils recorded on the school card which each child receives on entering school, a method of keeping the records which I recommend. All the teachers began the use of the method and their records were tabulated in June, 1913.

Miss Farley is to be commended for her thorough investigation of the method. She told me that she was convinced of its value and was willing to continue. She will permit the use of the ophthalmoscope.

Public School No. 186.

J. T. Nicholson, principal, Public School No. 186, had defective vision without his glasses. With the aid of a memorized Snellen card his vision became normal in a few minutes. In this way he learned something of the value of the Snellen card. After his personal experience with its benefits he more readily believed in the probability that the teachers by improving the vision of school children would prevent myopia. His teachers did not all record the vision until October, 1912.

On April 14, 1913, all the Snellen cards were removed and not replaced until June 16, 1913. The records of his teachers indicated a less number benefited than in Public Schools Nos. 6 and 183, where the Snellen cards were in use continuously for a longer time.

Miss Mary E. Sinnott, assistant principal, called my attention to the fact that the more experienced or better teachers benefited the vision of a larger number of children than did the teachers of less ability. Mr. Nicholson believed that the vision of the pupils in his school was benefited by the Snellen card. He is now willing that I use the ophthalmoscope for a more accurate investigation.

C. B. Jameson, principal, Public School No. 43, in March, 1913, introduced the method in his school on the recommendation of J. T. Nicholson, principal, Public School No. 186. Four teachers tested the vision, made the records, and used the Snellen card for myopia prevention without my supervision. It was only through the courtesy of J. T. Nicholson that I learned the facts. In June, 1913, Dr. John P. Conroy, district superintendent, kindly loaned me the records of the vision of the pupils tested, in March and again in June, 1913, by the teachers of Public School No. 43. The results were good. It seems probable that the method could be introduced successfully in other schools without my supervision.

W. A. Boylan, principal, Public School No. 46, introduced the Snellen cards in 1912. He has incurable myopia acquired in school. With the aid of the Snellen card, I improved his vision, without his glasses, fivefold in ten minutes. He has cooperated with me as much as he could, but only two teachers submitted records, June, 1913.

Miss J. Hiesel, E6A, submitted the best records which I have seen in ten years. Of twenty-seven defectives all were improved and twenty-five obtained normal vision in both eyes. She described how one incorrigible, and one truant, became good students after their eyes were relieved of pain and discomfort by the use of the Snellen card. I attended one of her daily exercises in distant vision with the aid of the Snellen card, witnessed the enthusiasm of all the pupils in the game, and learned much of the possibilities of the method for improving defective vision and preventing myopia.

Records.

Table I.—Summary of the records of the vision of the pupils made by the teachers of five New York city schools.

Note that in Public School No. 186 the Snellen cards were removed from all the class rooms April 14, 1913, and replaced June 16, 1913.

Totals 5,700 3,206 58 2,026 61 1,023

All the principals and all the teachers, in the beginning, were sceptical. After they used the method and investigated the results in the class rooms, they became convinced that the use of the memorised Snellen card improved the vision of the school children. They do not understand it.

Conclusions.

1. All investigators, I believe, have published that previous efforts to lessen defective vision or prevent myopia in schools have failed.

2. One hundred and twenty one teachers in the schools of New York City have lessened appreciably the number of pupils with defective vision. Note in the accompanying records that over 1000 pupils with defective sight obtained normal vision in both eyes.

3. Thirty-two teachers prevented the vision of all their pupils from becoming worse.

4. Myopia was prevented by teachers. 938 St. Nicholas Avenue.

A STUDY OF STILLBIRTHS.

By Lee W. Thomas, M. D.,
New York,
Physician to Outpatient Department, Bellevue Hospital; Physician to the Committee for the Reduction of Infant Mortality of the New York Milk Committee.

Definition. There are as many definitions of the term "stillbirth" as there are health departments and legal, medical, and statistical societies which at various times are called upon to define the term. These numerous definitions are divided into two main classes, the medical and legal. In brief, the medical definition is, the birth of the product of human conception which does not have life when entirely separated from the mother's body, but which has reached such a period in the uteroestation that had it been born alive it would have lived. Both definitions would have to be further elucidated as to the definite signs of life. The legal definition would require a detailed description of a viable fetus.

To illustrate the diversity of opinion as to the meaning of the term "stillbirth" I will quote some of the definitions of the term as given by different cities, States, and countries, and by medical and statistical societies: New York State: "A child born dead, having never breathed and having attained sufficient development to determine sex." New Orleans, La.: "Born dead." Baltimore, Md.: "One that has not breathed." Bridgeport, Conn.: "One that does not breathe." Pittsburgh, Pa.: "One that has not breathed at all nor shown any signs of life." Troy, N. Y.: "Born lifeless." Boston, Mass.: "Child who did not breathe after birth." Oakland, Cal.: "Born dead at or near full term." St. Louis, Mo.: "Child born dead." Washington, D. C.: "A fetus which after birth does not breathe." Philadelphia, Pa.: "A child born dead." Worcester, Mass.: "Child born dead." Nashville, Tenn.: "One born dead." Chicago, Ill.: "A baby born dead. Without life." New York, N. Y.: "Infant born dead, which has never breathed." Buffalo, N. Y.: "Fetus born dead." Reginald Duffield, M. A., A., statistician, Royal Society of England: "A stillborn child means a child whose body at birth measures not less than thirteen inches (thirty-two centimeters) in length from the crown of the head to the sole of the heel, and who, when completely born (the head, body, and limbs of the child, but not necessarily the afterbirth, being extruded from the body of the mother) exhibits no sign of life; that is to say, whose heart has ceased to function, as demonstrated by the absence of pulsation in the cord at its attachment to the body of the child and absence of any heart sounds or impulses." American Public Health Association: "For registration purposes stillbirth should include all children born who do not live any time whatsoever, no matter how brief, after birth."

From a study of these definitions I have formulated the following, which I believe will serve the purpose for which the registration of stillbirths is intended. The term "stillbirth" applies to the birth of the product of human conception, at any period of uteroestation which, when entirely separated from the mother's body (head, body, and limbs, but not necessarily the placenta or membranes) shows no sign of life, sign of life being either cardiac pulsation or sounds, breathing or crying. Later,
under the heading Purpose of Registration, I will give my reason for this definition.

**Frequency of Stillbirths.** The stillbirth rate in 1,000 of the births—living and still—reported in New York city for the period 1906 to 1912, inclusive:

<table>
<thead>
<tr>
<th>Period</th>
<th>Average 1906-1912</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>1906</td>
</tr>
<tr>
<td>Manhattan</td>
<td>56.8</td>
</tr>
<tr>
<td>Bronx</td>
<td>57.6</td>
</tr>
<tr>
<td>Brooklyn</td>
<td>56.5</td>
</tr>
<tr>
<td>Queens</td>
<td>56.9</td>
</tr>
<tr>
<td>Richmond</td>
<td>57.3</td>
</tr>
<tr>
<td>C. of N. Y.</td>
<td>56.1</td>
</tr>
</tbody>
</table>

C. of N. Y. = Census.

You will notice that the rate is a little lower in 1910, the census year. This is due to an overesti-

mation of the population in the previous and succeeding year.

From a study of records of pregnant women who received prenatal care from the Committee for the Reduction of Infant Mortality of the New York Milk Committee, which is conducting an experiment to determine the value of teaching expectant mothers the hygiene of pregnancy and the care of the newborn infant as a means of reducing the number of stillbirths and deaths of early infancy, it is found that one in every twenty-eight pregnancies results in a stillbirth at some period of gestation. And I believe this estimate of the frequency of stillbirths is low, as most of these women are registered after the fifth month of pregnancy. Estimated on the reported pregnancies (births and stillbirths) for 1912 in New York city, one in every twenty-two pregnancies results in a stillbirth. From a tabulation of the last previous pregnancies of 784 multiparae registered for prenatal care with the New York Milk Committee, I find that one in every fifteen pregnancies resulted in a stillbirth.

**Relation of Sex of Child to Frequency of Stillbirths.** According to Newsholme, the male stillbirths outnumber the female stillbirths, probably owing to the greater difficulty in childbirth. Thus in ten years, 1865 to 1875, they were, in France, 144; Italy, 140; Belgium, 135; Sweden, 133; and Prussia, 129, to every 100 female stillbirths. In Berlin, in 1865, the proportion of males to females among the stillborn was 137 to 100; among the living, 104 to 100. In Hamburg, in 1869, the proportion of males to females among the stillborn was 125 to 100; among the liveborn, 107 to 100. In New York city, in 1911, the proportion was 139 male stillbirths to 100 females; while the proportion in living births was 106 males to 100 females.

**Influence of Illegitimacy.** In his book on Vital Statistics, Newsholme states that the proportion of stillborn is greater among the male illegitimate than among the male legitimate children. This is shown by the following figures:

<table>
<thead>
<tr>
<th>Country</th>
<th>Period</th>

</tbody>
</table>

**Influence of Season on Number of Stillbirths.** The following table shows the percentage of stillbirths occurring in each month, from June 1st to December 31st, in the Borough of Manhattan; also month of gestation of occurrence.

This tabulation shows that the third month stillbirths are most frequent in July and October; fourth month, in July and August, fifth month, July and October; sixth month, November and December; seventh month, June and December; eighth month, August and September; the ninth month and full term predominates in June and December. This table shows that the season of the year bears no particular relation to the frequency of child-births.

**Period of Uterogestation of Occurrence of Stillbirths.** The following table is prepared from 261 stillbirths occurring among 783 previous pregnancies of women now receiving prenatal care from the New York Milk Committee.

<table>
<thead>
<tr>
<th>Month of Uterogestation of Occurrence</th>
<th>Ninth and full term</th>
</tr>
</thead>
<tbody>
<tr>
<td>Number</td>
<td>3</td>
</tr>
<tr>
<td>Percentage</td>
<td>15.15</td>
</tr>
</tbody>
</table>

This table shows that stillbirths are most frequent in the third month of pregnancy, next most common in the second month, and next in order come the ninth, seventh, and fifth months. There seems to be little difference in the frequency of stillbirths in the first, sixth, and eighth months. The logical explanation of the relative high number of stillbirths in the second, third, fourth and seventh month of pregnancy is that the greatest developmental changes of pregnancy occur during these months. The large number occurring in the ninth month are due to abnormal delivery and congenital abnormalities of the child. To prove the accuracy of the foregoing table, I compared it with the figures of the stillbirths occurring in the last previous pregnancy, and found that the percentages for each month of uterogestation were practically the same.

Out of a total of 1,867 stillbirths reported in Manhattan for the period from June 1st to December 31st, 1,331, were reported as occurring during the viable period (seventh month on). This shows that 71.39 per cent. of these stillbirths had a chance
to be born alive had the mother received proper prenatal and natal care. This statement is borne out by the fact that the Committee for the Reduction of Infant Mortality of the New York Milk Committee in its experiment of educating expectant mothers in prenatal hygiene has found among 1,534 pregnancies, a stillbirth rate of 35 per 1,000, as against the Borough of Manhattan rate of 46.5 per 1,000 pregnancies reported during the same period. If the committee's rate had prevailed throughout the entire city, the total number of stillbirths would have been 4,959, as against the actual number of reported stillbirths, 6,614. If these 1,331 stillbirths, born after the viable age, had lived, it would have increased the births one per mille of the population of Manhattan, and added thirty-three births to every 1,000 living births reported for the same period. This, I believe, is a good index to the character of prenatal and natal care that our New York mothers receive, and should awaken all institutions interested in infant welfare and medical work to try to bring about a higher standard of efficiency on the part of those engaged in the practice of obstetrics.

Attendance at Confinement. The attendance at childbirth seems to have some relation to the frequency of stillbirth as shown by the following chart:

<table>
<thead>
<tr>
<th>Chart Showing the Percentage of Total Living Births and of Total Stillbirths, Attended by Physicians, Hospitals, and Midwives.</th>
</tr>
</thead>
<tbody>
<tr>
<td>White—Percentage of total living births. Black—Percentage of total stillbirths.</td>
</tr>
</tbody>
</table>

| Physicians | 47.4 |
| hospitals | 14.4 |
| Midwives | 35.2 |

This chart shows that something is wrong, either in the efficiency of those attending at confinement or else in the system of registration of stillbirths. It will be observed that the physician reports 69.42 per cent. of all stillbirths reported, and only 47.4 per cent. of the living births reported. This means that for every one per cent. of total living births reported, he is reporting 1.5 per cent. of total stillbirths reported. The hospital ratio is even greater, being one per cent. as to 1.7 per cent.

The figures show that the ratio is reversed in the case of the midwife, as for every one per cent. of total living births reported, she is reporting only 0.16 per cent. of stillbirths reported. This would give the reader the impression that the midwives of Manhattan were doing better obstetrics than either the hospitals or the physicians. I do not believe this to be true. But the physicians and hospitals are responsible for these figures, and not for the actual conditions, as it is a known fact that physicians do a large consultation practice with midwives and often take the responsibility of reporting stillbirths at which they do not actually attend professionally. The fact remains that, statistically, the physicians and hospitals are charged with a greater proportion of stillbirths to total births than midwives, and if they are willing to remain sponsors for midwives who are not sufficiently well trained to detect abnormalities or conditions which require interference in delivery, we shall have to continue to charge the stillbirths to the physicians; or else conduct a campaign of education among physicians and get them to report these stillbirths as they should be reported, as occurring under the care of midwives and reported by physicians.

The following table shows the

<table>
<thead>
<tr>
<th>Attendance at Stillbirth by Hospital, Physician, and Midwife in Relation to Utero-Gestation Period.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Month of gestation</td>
</tr>
<tr>
<td>---</td>
</tr>
<tr>
<td>Not given</td>
</tr>
<tr>
<td>First</td>
</tr>
<tr>
<td>Second</td>
</tr>
<tr>
<td>Third</td>
</tr>
<tr>
<td>Fourth</td>
</tr>
<tr>
<td>Fifth</td>
</tr>
<tr>
<td>Sixth</td>
</tr>
<tr>
<td>Seventh</td>
</tr>
<tr>
<td>Eighth</td>
</tr>
<tr>
<td>Ninth</td>
</tr>
<tr>
<td>Full term</td>
</tr>
</tbody>
</table>

In studying the foregoing table one must take into consideration that physicians who do a large consultation practice with midwives are called upon to register stillbirths, although they do not do the actual delivery. This will increase greatly the number of stillbirths reported as attended by physicians in the ninth month. I might mention that it is not an uncommon occurrence for physicians to certify a stillbirth when they have never seen either the mother or the stillbirth. This table shows that the number of cases attended by hospitals and physicians in the ninth month and full term is much greater than that attended by midwives, but in considering the percentage totals of each attended in the ninth month and full term there is very little variation, being: Hospitals, 50.33 per cent.; physicians, 46.46 per cent.; and midwives, 49.50 per cent. It also appears that when comparing the percentage totals attended by each, the midwives attend comparatively more in the third and eighth month of pregnancy than do the hospitals or physicians. The physicians attend more of the seventh month stillbirths. Except for the foregoing facts, this table would lead one to believe that midwives are doing as good obstetrics as the hospitals and physicians. I must confess some disappointment in not finding that the percentage totals of the ninth month and full term stillbirths were not much higher for midwives than for either hospitals or physicians.

Actual Causes of Stillbirths as Certified to on Returns. Out of a total of 1,867 certificates of stillbirth examined at the Department of Health of Manhattan, 775, or 41.5 per cent. of the certificates did not contain information as to the cause of the stillbirth. This is due in part to the fact that many
persons reported stillbirths on the old form, which under "cause" reads: "Cause, if known." This common method of reporting was unfortunate. The new form, however, does not contain the words "if known," and the physician or other persons reporting stillbirths are no longer relieved of the responsibility of ascertaining and reporting the cause of stillbirth in each case. The following table shows the negligence of those engaged in the practice of midwifery in reporting the cause of stillbirths:

**TABLE SHOWING RELATION OF ATTENDANCE AT STILLBIRTHS TO REPORTING OF CAUSE.**

<table>
<thead>
<tr>
<th>Reported by</th>
<th>Cause given</th>
<th>No cause given</th>
<th>Total reported</th>
<th>Percentage cause given</th>
</tr>
</thead>
<tbody>
<tr>
<td>Physician</td>
<td>726</td>
<td>433</td>
<td>1,159</td>
<td>37.0</td>
</tr>
<tr>
<td>Hospital</td>
<td>369</td>
<td>156</td>
<td>525</td>
<td>33.5</td>
</tr>
<tr>
<td>Midwife</td>
<td>35</td>
<td>76</td>
<td>111</td>
<td>68.5</td>
</tr>
<tr>
<td>Coroner</td>
<td>12</td>
<td>10</td>
<td>22</td>
<td>90.1</td>
</tr>
</tbody>
</table>

Total: 1,092; 775; 1,867

The table shows that, with the exception of the coroner, the midwife is most lax in reporting causes of stillbirth. This is due to her lack of knowledge of pathological conditions. The physician is next most negligent, and the fact that he reports a large number of stillbirths which occur under the care of midwives may account for this. The hospital has a better chance to study the pathology of cases, and there would seem to be no good reason for its failure to report the cause of stillbirth in thirty-three per cent. of its cases. The table also shows the need of education all along the line as to the importance of accurate and complete vital statistics. The following are the causes, as certified, of the stillbirths occurring in the Borough of Manhattan for a period of seven months, beginning June 1, 1912. These terms were copied from the certificate, and any errors were allowed to remain in order to give the reader a clear idea of the terms used. I have classified these causes, but some may be misplaced, owing to a lack of understanding as to the meaning of the terms used.

This needs no comment, and I will pass on to the registration of stillbirths.

**History of Stillbirth Registration.** The following table is taken from the report of the Special Commission on Infant Mortality of the Royal Statistical Society, and gives in succession the dates when different countries and states adopted the registration of stillbirths:

Registration of stillbirths is not compulsory in England, Wales, Ireland, Scotland, Gibraltar, Cyprus, Hong Kong, Gambia, Orange Free State, Sierra Leone, Jamaica, New Brunswick, New South Wales, New Zealand, Queensland, South Australia, Tasmania, Victoria, Denmark, Mississippi, New Mexico, North Carolina, and Virginia.

**Methods of Registration.** At present there is no uniform method of stillbirth registration. In Spain registration is necessary for burial purposes only. In Italy stillbirths are registered as births, and this method is also used in Sweden. In France and Germany stillbirths are registered as births and deaths; in Austria, Western Australia, and Ontario, as deaths only. In Norway and Denmark they are registered as stillbirths only. In the United States the methods of reporting stillbirths of different cities and States are as follows:

**Stillbirths Reported as Deaths.**

- **Montana.**
  - Stillbirths Reported as Births.
  - Los Angeles, Cal.
  - Milwaukee, Wis.
  - Cincinnati, Ohio.
  - Iowa.

- **Stillbirths Reported as Births and Deaths.**
  - Oakland, Cal.
  - Grand Rapids, Mich.
  - Grand Forks, N. Dak.
  - Concord, N. H.

- **Stillbirths Reported Separately.**
  - New York city, New York state.
  - Cleveland, Ohio.
  - Buffalo, N. Y.
  - Paterson, N. J.

- **New Orleans, La.**
  - New York, N. Y.
  - Chicago, Ill.
  - Baltimore, Md.
  - St. Louis, Mo.
  - Washington, D. C.
  - Detroit, Mich.
  - Nashville, Tenn.
  - Rochester, N. Y.
  - Bridgeport, Conn.
  - New Haven, Conn.
  - Lawrence, Mass.
  - Indianapolis, Ind.
  - Denver, Colo.
  - San Francisco, Cal.
  - Richmond, Va.
  - Cambridge, Mass.
  - Springfield, Mass.
  - Mississippi.
  - Indiana.
  - Connecticut.
  - Massachusetts.
  - Kentucky.
  - California.
  - New Jersey.
  - Colorado Springs, Colo.
  - Atlanta, Ga.
  - Providence, R. I.
  - Harford County, Va.
  - Lowell, Mass.
  - Virginia.
  - Kansas.
  - Wisconsin.
  - Texas.
  - Ohio.
  - North Carolina.
  - Washington.
  - New Hampshire.

*Registration not compulsory.*

The method of registration and reporting is of vital importance in calculating infant mortality. The stillbirth has no direct bearing upon the infant mortality, as the stillbirth has never been a living human, and therefore should not be recorded in either the births or the deaths. But the stillbirth has an indirect bearing upon mortality, as I believe the pathological conditions which are associated with stillbirths are directly responsible for the deaths of infants now reported as dying from congenital and ill defined causes.

**Purpose of Stillbirths Registration.** The registration of stillbirths furnishes statistics for:

1. Study of one great cause of depopulation.
2. Determination of the fecundity of the population.
3. Furnishes a source of study to determine the causes of deaths occurring in early infancy.
4. Is a guide to the proficacy of those engaged in the practice of midwifery.
5. Places a higher value on infant life.
6. Removes a motive for infanticide.
7. Acts as a check on the practice of criminal abortionists.
8. Is legal evidence of the productiveness of woman.
9. Is a safeguard to the physician who finds it necessary to induce an abortion or premature labor.
10. Assures the proper disposal of the dead.

These are the most important purposes served by the registration of stillbirths, and they are of vital importance to society.

**Laws Governing Registration of Stillbirths.** In order to obtain the greatest benefit from a statistical standpoint, and also from a social and economic standpoint, it is necessary that all countries, States, and cities should have uniform stillbirth registration laws. The law should contain a clear, concise definition of the term “stillbirth,” a statement of the registration act, and a penalty for violation. I take the liberty of presenting a draft of a law which I believe, if enforced, would obtain every item of information for which stillbirth registration is intended.

**A LAW GOVERNING THE REGISTRATION OF STILLBIRTHS.**

The term “stillbirth” shall apply to the birth of the product of human conception, at any period of uterine pulsation, which when entirely separated from the mother’s body (head, body, and limbs, but not of necessity the placenta or membranes) shows no sign of life. Signs of life are cardiac pulsation or sound breathing or crying. It shall be the duty of the parents of any stillbirth in the city (if there are no parents alive who have made such report, then the next of kin of said stillbirth), and of every person present at such stillbirth within forty-eight hours after such stillbirth, to report to the Department of...
Health in writing, the date, borough, and street number of said stillbirth; the sex, color, period of uterogestation, time of death (before or during birth of such stillbirth), causes of stillbirth, predisposing and actual; name, residence, birthplace, and age of parents, occupation, maiden name of the mother; number of previous pregnancies, number of living births, and number of children living at present. It shall be the duty of physicians and midwives to keep a registry of the stillbirths at which they have attended professionally, which shall contain the data of stillbirth, borough, street, and number where such stillbirth took place, the sex, color, period of uterogestation, and time of death of the stillbirth; also the causes of stillbirth, predisposing and actual; the number of previous pregnancies, number of living births, number of children living at present: the name, residence, birthplace, and age of parents, occupation of the father, maiden name of the mother; and to file a copy of the said stillbirth record with the Department of Health in the borough office of the borough where the said stillbirth occurred, within forty-eight hours after such stillbirth, upon blank forms furnished by the said department. It shall be the duty of said physicians and midwives to certify that they attended personally at the birth of the stillbirths so reported, and that all of the other facts stated in the copy of the said registry are true to the best of their knowledge, information, and belief.

The penalty for violation of this law shall be the same as for violation of death registration law.

Form for Registration of Stillbirths.

Certificate of Stillbirth.

The term "stillbirth" shall apply to the birth of the product of human conception, at any period of uterogestation, which when entirely separated from the mother's body (head, body, and limbs, but not of necessity the placenta or membranes) shows no signs of life. Signs of life are cardiac pulsation or sounds, breathing or crying.

Discussion. The following are items not generally called for in stillbirth certification blanks:

Character of premises where stillbirth occurred:

time of death of fetus: predisposing causes of death;

occupation of father and mother; number of previous pregnancies; number of living births, and number of children living at present; and the status of the attendant and of the person making report. Information as to character of premises where stillbirth occurred is necessary in order to determine the influence of housing conditions on the frequency of stillbirths; also information as to the stillbirths occurring in hospitals. Insertion of the clause, "time of death of fetus," will give information as to the proficiency of the medical attendant, and partially fix the responsibility for a large number of stillbirths. Predisposing causes of stillbirth should be given, as they furnish information as to the medical and social conditions, which can be corrected by those interested in prenatal work, and allow the mother the opportunity to have normal subsequent pregnancies. Occupation of father and mother should be stated in order to determine the influence of occupational diseases, and the influence of employment of pregnant women upon the causes and frequency of stillbirth. The items "number of pregnancies," "number of living births," and "number of children living at present" will give valuable information as to the individual case needing care and instruction during subsequent pregnancies; also information as to the frequency of stillbirths. The status of the medical attendant and the person making report are necessary to fix the responsibility for stillbirths, and to do away with physicians reporting stillbirths occurring under care of midwives.

Time of Registration of Stillbirths. A laxity in reporting stillbirths early puts a low valuation on stillbirth registration and upon the proper disposal of the dead. The following table shows for 1,281 cases the relation of attendance at confinement to the time elapsing between the date of occurrence and date of reporting of stillbirths.

In New York city stillbirths should be reported within three days from date of occurrence. You will notice that 21.78 per cent. of the stillbirths are reported after the legal time limit. That physicians and hospitals are most lax in reporting stillbirths within the prescribed time limit. If this condition exists in New York city, where birth and death registration is considered almost perfect, the conditions in other cities, States, and countries, must exert a great influence on the completeness of the stillbirth registration and upon the proper disposal of the dead.

Disposal of the Remains of Stillbirths. In investigating the stillbirth records of New York for a period of seven months I was surprised to find that little attention was paid to the disposal of the remains of stillbirths. The coroner reported stillbirths which were found in street cars, ash and garbage cans, in the river, parks, and almost every conceivable place. Certificates stated that the remains had been put in toilets and disposed of in other improper ways. Hospitals generally retain the bodies for anatomical purposes. This all tends to put a low valuation on child life, stillbirth registration, and disposal of the dead. In order to determine the proper method of disposing of the remains of a stillbirth in New York city, I took the remains of
a stillbirth to the registration office and asked permission to retain the body for anatomical purposes. I was immediately confronted with the fact that I had violated the law by removing the remains from the place of death, and that it would be necessary for me to obtain a written permit from the parents in order to retain the body. After presenting the permit at the registration office a regular burial permit was given me, with the warning that I should keep it, so that if occasion demanded I should have evidence to prove that I had disposed of the remains in a proper manner. This procedure is entirely correct, but will hardly gain a complete registration of stillbirths: and I am quite sure it is not the procedure used in cases where persons have answered the question. "Where buried?" in the stillbirth record by stamping with a rubber stamp: "Body retained for anatomical purposes." Perhaps other physicians have had the same experience as I have had, and are avoiding the unpleasantness and loss of time by reporting stillbirths late or not reporting them at all.

Expense of Proper Disposal of Stillbirth Remains. The expense of proper disposal of the remains of stillbirths is a hardship which comes at a time when the family purse has already been greatly taxed, and this may also be partly responsible for the neglect of parents and doctor to register the stillbirth. The doctor is often called upon to dispose of the remains. By doing so he is violating the law, but he sees the financial condition of the family and takes the responsibility. But does he in such cases register the stillbirth? I believe not. To correct this unsatisfactory condition the departments of health of cities should have a crematory where bodies of stillborn infants can be disposed of when properly registered and the consent of the parents are obtained. This would mean the saving of thousands of dollars to poor people in a city like New York, and encourage a better spirit of cooperation among physicians with the health authorities in establishing registration, and at the same time promote prompt and complete returns and the proper disposal of the dead.

Conclusions.
The foregoing study presents the following facts:
That the definition of the term stillbirth is of great importance from a statistical standpoint, as it may cause to be included or excluded a large number of cases in statistical data regarding births, deaths, and stillbirths.
That stillbirths are far more frequent than vital statistics indicate at present.
That the following factors influence the frequency of stillbirths: The sex and legitimacy of the child, the attendance at confinement, and the period of uteroestagenation of occurrence of birth.
That the season of the year has little influence on the frequency of stillbirth.
That the number of stillbirths occurring during the viable period is relatively high.
That the high stillbirth rate can be reduced by the systematic education and supervision of expectant mothers.
That there is negligence in reporting causes of stillbirths, and that this negligence greatly lessens the value of stillbirth registration.

That stillbirth registration is becoming recognized in all countries.
That there is need of uniform stillbirth registration laws which shall define the term and establish a standard for registration and reporting.
That the methods employed in the registration and reporting of stillbirths affects the value of the vital statistics from both a medical and social standpoint.
That the methods of disposal of the remains of stillbirths influence the registration of stillbirths.

477 Bainbridge Street, Brooklyn.

REPORT OF AN IMBECILE WITH PARESIS.

By J. Allen Jackson, M.D.,

Chief Resident Physician, Philadelphia Hospital for Insane.
The following case is of interest for three reasons: First, because it is the first case of its kind on the records of the Philadelphia Hospital for the Insane; second, because no record of any other case has been found; third, the pathology of this condition would be rather interesting on account of the fact that in paresis the cells of the highest type of development are involved; which cells are lacking in imbecility.
C. O., thirty-six years of age, machinist by occupation, was admitted to the Philadelphia General Hospital January 25, 1900, and transferred to the Philadelphia Hospital for the Insane February 11, 1900.

Family History: Patient's father died from senility; mother died as a result of burns. One sister was stillborn; two brothers and one sister living and well. No history of insanity or other nervous diseases in the family.

Past Medical History: During his youth, patient suffered from measles and severe attacks of tonsillitis, and about a year and a half previous to admission to the hospital he was kicked in the head by a horse.

Social History: Patient was born in this country and received a common school education, but was never bright in school. After leaving school he worked steadily and regularly until about a year and a half previous to his admission to the hospital; at which time he began to drink very heavily and used tobacco excessively. He never married; was a chronic masturbator, and indulged incessantly in this habit for one and a half years; during this time, he was slovenly in his habits and refused to do any work.

Present Trouble: Was always kind and generous, and would talk reasonably with his people until one month previous to admission. He suddenly changed all his habits and manners, became very dirty about his person, lost all interest in his surroundings and relatives, would sit for a long time by himself, and would not converse with anyone; he also became very selfish—would take things from everybody and, if he were not watched at mealtimes, would steal food from the plates on the table. He slept a great deal and refused to work. He was arrested once and sentenced to three months imprisonment, but served only two days; was again arrested when he was found attempting to set fire to his house; was finally picked up by the police as a vagrant because he was found wandering about the streets and apparently had no home, and was then sent to the Philadelphia General Hospital.

Initial mental examination made at the time of his admission to the Philadelphia Hospital for the Insane showed that patient was disoriented, confused, and could give no account of himself. He denied hallucinations, illusions, and delusions. He appeared to be happy and contented. The physical examination showed that patient presented many features of a high grade imbecile. His
head was egg shaped; face was asymmetrical. Pupils were unequal, the left was larger than the right; both pupils reacted promptly to light and accommodation; there was internal strabismus of both eyes. Tongue was protruded in the median line and was tremulous. Knee jerks were exaggerated; equal on both sides. Sensation was not impaired; gait and station were normal. Examination of the lungs was negative; there was slight hypertrophy of the heart and slight accentuation of the aortic and pulmonary second sounds.

Five months after his admission to the hospital a diagnosis of paresis was made. At that time there was an impediment in his ordinary speech, slurring on some catch words; there were some tremors of the lips when talking; pupils did not react to light, but reacted to accommodation, and knee jerks were slightly increased. Fifteen months later patient was examined in consultation with Dr. Charles W. Burr. At that time he was grandiose, and made the following statements: "H. C. gave me a million dollars. Mr. C. gives me everything I want and I am getting cigars and tobacco and everything else, and I got pipes and tobacco to give to the boys in the dining room. No sir, I'm not sick at all. I'm going to get people to work at it now. No sir, I'm well and happy. I'm going to have a full orchestra. I've got a good recommendation here. I fix the tables up in the dining room nice, and everything else. I got everything, and I'm going to give them neckties, pins, and all. I'm going to have some birch beer. You phone to B. and D. and E., and tell them to send me some birch beer. No sir, I love tobacco, and I'm going to get plenty of it, too. I'm going to get everybody a bag of tobacco to-day, etc."

Patient was later confined to bed (date not recorded), and two months later succumbed. Clinically, the cause of death was regarded as pulmonary tuberculosis. Necropsy was not obtained.

THE PRESENT STATUS OF SERUM THERAPY.

BY WALTER B. JENNINGS, PH. B., M. D.

New York.

Serum therapy, as the name implies, means treatment by blood serum and represents one of the recent discoveries of modern scientific medicine.

It has been said that the progress made in medicine (scientific medicines) during the last fifty years (1850-1900) has done more for real advancement than all the work of all physicians from the time of Hippocrates down to Edward Jenner. Since the dawn of medicine great things have been accomplished, but medical science never sprang forth full born as Athene did from the head of Zeus. Each step forward has been a natural and logical growth. Every advance in the progress of mankind depends upon the achievements of experimental science, as well as laboratory research. This is especially true of serum therapy, for without laboratory research, and particularly bacteriology, there could have been no such thing as serum therapy. Without the researches of Behring and of Roux we would not possess the lifesaving antitoxine which has practically robbed diphtheria of its terrors. At the same time, Behring and Roux could not have done their work without the discoveries of the diphtheria bacillus, the work of Klebs (1883) and Loeffler (1884). Yersin, Calmette, and Borrel, in producing an antitoxine serum for bubonic plague, were indebted to Kitasato (1894) for discovering the pest bacillus. In 1884, Nicolaier produced tetanus in mice and rabbits by subcutaneous injections of earth, and about 1889 Behring and Kitasato were the first to show the possibility of immunizing animals against tetanus infection.

Serum having certain protective properties against some diseases have been used successfully in both animals and man. The serum from the blood of the rabbit, horse, guineapig, goat, or of man is generally used. Generally the blood serum of an animal which has passed through a certain disease is taken, but in some cases normal blood serum is effective. If the animal has not had a certain disease, it may have been inoculated with certain bacterial products which causes its blood serum to contain some protective substances against that particular toxine of the bacteria used in the experiment.

The chemistry of blood serum is an interesting study. Dr. A. A. Epstein investigated eighty sera: thirty-nine cases from the blood and forty-one from effusions. He says that, normally, blood serum varies but little in its chemical composition in health, but marked variation occurs in many diseases. He thinks the striking feature was the variation of the serum in relation to its globulin content, which was markedly increased in cardiac diseases, pulmonary affections, diabetes mellitus, and parenchymatous nephritis. The globulin content of the serum was normal or below normal in tuberculosis, diabetes insipidus, and chronic interstitial nephritis. He says also that in those diseases in which the globulin was increased there appeared to be an accumulation of water and salt.

Theory of Serum Treatment.

This brings us to the subject of immunity, but so vast is the subject and so many are the theories regarding it that it will be impossible for us to consider it except so far as to present a mere outline which will directly apply to the subject at hand.

"The protective substances," says Dr. W. H. Park, "held in solution in the blood serum are clearly apparent in their effects, either in preventing the increase of the bacteria or neutralizing the toxic action of their products; chemically, however, they are but little understood, and although some of them have been shown to be to a large extent specific, still we have no knowledge of any chemical difference between them." In a general way one might think of these substances as globulins, but very complex. As a rule, the serum should be given before the bacteria have multiplied to a very great extent within the body. The immunity from the serum lasts from a few days to several months. The theory of Metchnikoff, or white blood cells (leucocytes) attacking the bacteria, cannot be entirely accepted, and only partially explains the phenomenon. Ehrlich believes the antitoxine to be a part of the cell substance which combines with the toxine and neutralizes it. Another theory is that the toxine in some way is changed in the body into antitoxine. It may be that, with our present knowledge, none of the theories is entirely correct.

Specific Serums.

Under this heading we will divide serums into two classes, 1. normal serum, and 2. immunized serum.
1. Normal Serum. By normal serum we mean the blood serum of man or an animal that has not suffered from any given disease. Normal blood serum has been used in hemorrhagic disease with remarkable success of late. This treatment represents one of the recent advances in the practice of medicine, for many lives have been saved which would undoubtedly have been lost under the older methods of treatment. The use of human or other blood serums in cases of hemophilia has proved to be a measure of great value. Dr. J. E. Welch, in a preliminary report of his work at the New York Lying In Hospital, read before the New York Academy of Medicine a few years ago, proved the value of normal serum in hemorrhagic disease of the newborn, i. e., bleeding of the cord, subcutaneous bleeding, bleeding of the bowels, etc. Barringer reports a case of unilateral hemorrhage of the kidney which was controlled by the injection of human blood serum supplied by the patient's brother. V. M. Reichard reports a case of spontaneous hemorrhage in a child, thirty-six hours old, in which bleeding from the bowels and vomiting of blood were controlled by the use of normal horse serum (dose, fifteen c.c., subcutaneously). The infant fully recovered. M. J. Perkin reports the case of a boy, three years old, cured by diphtheria horse serum. C. Koch and W. Klein (Gynäkologische Rundschau, 1912) report the case of a sixteen year old girl whose second and third menstruations pointed to hemophilia. The menses lasted three weeks, with bleeding from nose and gums. Debrinated blood from a normal post partum patient was injected, and there was no further bleeding. They think it possible that the physiological leucocytosis in the parturient woman may have aided in the cure. Claybrook suggests that the usually accepted conception of this condition may be wrong; that the trouble is not with the blood itself, but may be due to a condition in the intima of the vessels. He believes the intima secretes a substance that agglutinates and seals up the broken ends of the vessels, and thus stops the bleeding. This theory is not entirely correct, and does not explain the effect of the injected serum. Hemorrhages complicating typhoid fever have been reported in which serum injections controlled the bleeding.

Transfusion or infusion of blood might be briefly spoken of in considering this subject; but it not only makes use of blood serum, but whole blood as well. It has been practised for surgical shock and collapse from hemorrhage, gas poisoning, and septic conditions for as long as one hundred years or more. Tillmann (Leipzig) once said: "I fully agree with Bergmann and others that transfusion is not only a useless, but a dangerous operation." Since Tillmann's time, however, we have made much progress, so that to-day transfusion can be performed safely and successfully. The increased knowledge of the physiology of the blood has shown that the dangerous and often fatal results were due to agglutinins in the blood serum of the donor. It has been found that individuals fall into definite groups in regard to so called isoagglutination, and Dr. M. Fishbein, of Chicago, describes an easy test which takes only half an hour. (Journal of the American Medical Association, September 7, 1912.)

2. Immunized Serums. (Antitoxins.) It has been found that the normal animal body responds to the injection of very small amounts of certain bacterial toxins by the formation of antitoxins which are antidotes to their respective toxins. This fact led to the production of curative serums.

1. Diphtheria antitoxine. Prepared from immunized horses by precipitation and other treatment of the serum albumins, a portion of the globulins and all inorganic salts being removed. It is a solution of the protective substances, together with a portion of the serum globulins. Its use is twofold: First to cure the disease; second to immunize those exposed to the disease. The dose, in the first instance is from 3,000 to 6,000 units, in the latter from 500 to 1,000 units, depending upon age. This serum has reduced the mortality enormously, as the following table taken from the New York city health department bulletin shows:

<table>
<thead>
<tr>
<th>Year</th>
<th>Number of cases injected</th>
<th>Case fatality</th>
</tr>
</thead>
<tbody>
<tr>
<td>1905</td>
<td>3,488</td>
<td>1.7 per cent.</td>
</tr>
<tr>
<td>1911</td>
<td>6,167</td>
<td>3.6 per cent.</td>
</tr>
</tbody>
</table>

2. Tetanus antitoxine. This possesses a distinct prophylactic value, but should be administered early, even before symptoms appear, although Dr. Irving S. Haynes reported two cases of tetanus treated with this antitoxine with recovery. The dose is 1,500 units—to combat symptoms, from 1,500 to 3,000 units every six to twelve hours. Dr. P. R. Torres (Buenos Aires) says that 120 c. c. of tetanus antitoxine should be the rule. He calls this the saturation dose.

3. Antimeningitic serum. This serum contains opsonins, bacteriolysins, agglutinins, and antiendothelines developed as the result of injecting sound horses with endotoxins, killed cultures, and finally live cultures of Diplococcus intracellularis (Weichselbaum). The medical profession is indebted for this to Dr. Simon Flexner, of the Rockefeller Institute, who first produced this serum (1907). It is for the treatment of cerebrospinal meningitis, and is administered by doing a lumbar puncture, removing some of the cerebrospinal fluid, and replacing it by the serum, in doses of twenty c. c., given early. Under serum treatment in this disease the mortality has been lessened to about one third of what it formerly was. Levy punctured the fontanelle, in a child 3½ months old, and passed a needle into the lateral ventricle. The infant recovered.

Dr. Simon Flexner, in discussing the report of his 1,300 cases of epidemic meningitis, says:

The mortality of this disease can be greatly reduced by the application of the specific serum treatment, and the extent of the reduction is determined by two main factors, the period of the disease at which subdural injections of the serum are begun and the age of the persons affected. In view of the fact that the average mortality during the pandemic was approximately seventy per cent., the gross reduction was somewhat less than two thirds. On the other hand, the statistics presented indicate that general early diagnosis and prompt institution of the serum treatment are capable of still further depressing the mortality.

Although at first regarded as doubtful, it appears that fulminating cases of epidemic meningitis are not wholly without the sphere of beneficial influence of the serum.

4. Antistreptococcus serum. This is at present supplied in two forms. The one is obtained from horses which have been treated with numerous strains of the ordinary streptococcii, such as are found in cellulitis, erysipelas, and purpural fever.
The other is a polyvalent serum obtained from horses receiving a typical streptococci from cases of endocarditis, pneumonia, etc. The dose is from twenty c. c. to 50 c. c. hypodermatically.

5. Antipneumococcus serum. This is a polyvalent serum from horses receiving numerous strains of pneumococci. Dose, from twenty c. c. to fifty c. c. F. and G. Klemperer have had promising results in six cases of pneumonia. All the patients had a decided fall of temperature in from six to twelve hours after subcutaneous injection of from four to six c. c. of the serum. E. N. Sill has used this serum in children with pneumonia from two to five years of age. (Dose, ten c.c.). Dr. Rowland G. Freeman, in his paper on Serum Treatment in Pneumonia, says:

As to the effect of the serum, there was in many cases an immediate change in the appearance of the child. Children that looked septic, were apathetic, with anorexia, after the injection, had a good color, were brighter, took the feedings better, and seemed much improved, although the condition in the lungs was unchanged.

In conclusion, he says:

The serum injection while apparently affecting favorably the course of the disease in some cases, appears to have no results in others; that in most cases there appears to be a better reaction on the part of the child after injection than before. It was usually followed by some reduction in leucocytes, and the percentage of the polynuclear leucocytes was also diminished.

6. Serum for influenzal meningitis (Flexner).

7. Antigonorococci serum. This serum is obtained from the blood of horses that have been inoculated with gradually increasing quantities of a toxine from the most virulent strains of gonococci obtained. It is not used in acute cases, but is of value in arthritis and other complications.

8. Serums of uncertain value. Under this head we will consider briefly some of the newer serums which have not been long enough used or not used in a sufficient number of cases to judge of their permanent value.

"Fetal serum in the onset of labor" (Rongy). In uterine inertia the serum was effective. Seven out of nineteen cases proved negative. In one case with threatened eclampsia the serum not only caused the onset of labor but all urinary symptoms (albumin and casts) cleared up after the first injection. Best reaction with small injection first, followed by large doses four to five hours later (five c. c., twenty c. c. after five hours) use three, four, five, or six doses. (New York State Journal of Medicine, March, 1913.)

E. Benjamin (Therapeutische Monatshefte, February, 1913) uses horse serum inactivated at 56° C. in scarlatina. He thinks that it almost invariably mitigates the disease into an abortive type. Dose, from five to seven c. c.; protection lasts from twelve to fourteen days.

Autoseroserotherapy in Serofibrinous Pleurisy (Journal of the American Medical Association, March 29, 1913). Dr. Maurice Fishberg, New York, says that it is devoid of danger. When the contents of the pleural cavity are found to be serous, the needle should be withdrawn completely, but when its point is brought to the subcutaneous tissue it should be injected then and there. Dose, two to five c. c. Re-
Note.

Serotherapy in Nephritis. The December, 1912, number of Revista de medicina y cirugía prácticas has an interesting article by M. M. Dominguez in which he refers to J. Teissier's method of serum treatment. He says that serum treatment in nephritis has passed the tentative stage into one that is practical and successful. The treatment consists of the subcutaneous injection of serum from the renal vein of the goat. The blood in this vein must contain the internal secretion of the kidney, if any exists, and clinical experience confirms this. Goat serum is less toxic and less likely to induce serum sickness than horse serum. No case of anaphylaxis has followed its use. Dominguez begins with doses of from ten c.c. to twenty c.c., repeated on the fourth or fifth day. In urgent cases the injection can be given every day.

140 Wadsworth Avenue.

THE MANAGEMENT OF PULMONARY TUBERCULOSIS,

With Special Reference to Those Patients Who May Be Successfully Treated While Following Their Vocations in the City.

By Louis Shalet, M.D.,

New York,

Attending Physician, Tuberculosis Clinics, Department of Health.

Pulmonary tuberculosis, as is well known, is a chronic, infrequently progressive disease, sometimes fatal, in the successful treatment of which the question is how best to avail one's self of the well known natural resistance of the body to the disease in order to overcome the attack of the tubercle bacillus and thus bring about a clinical cure. That this is far from unattainable is proved by the fact that while the great majority of people are pathologically tuberculous, only a very small percentage of the whole actually die of the disease. This being a fact, the problem is how to diminish that small number still more. The rational answer is by following and amplifying Nature's method. As there is no royal road to the treatment of tuberculosis so far, and it is very doubtful whether a specific cure for pulmonary tuberculosis, one that will destroy the germs in the tissues and thereby permit the healing of the lesion, such as mercury or arsenic in syphilis, will ever be found. It is much more logical though less poetic to suppose that tuberculosis will disappear in time just as smallpox and the plague have from civilization, namely by prevention and right living. For one thing, any agent that will kill tubercle bacilli in the body, suitably applied, would surely destroy much less resistant forms of parasitic vegetable life, and it is inconceivable that we shall ever come much nearer to directly antagonizing such a universal means of death as by the various infectious diseases, as well look for the elixir of life.

The diagnosis of clinical pulmonary tuberculosis is, in the great majority of cases, not much more difficult, if one goes about it the right way, than the diagnosis of typhoid fever—the history and clinical symptoms, the physical signs, the proper examination of the sputum, the Röntgen ray, and finally tuberculin injected subcutaneously, will assist to properly diagnosticate practically all cases; and this diagnosis contrary to the usually dictum is not usually the discovery of a new infection by any means, but that of a first and more often a second relapse of a comparatively long standing clinical pulmonary tuberculosis. The first infection "cured," itself unknown to anyone, even the patient. The relapse that followed it consequent on disregard of simple rules of health was probably overcome while the patient was temporarily living a proper hygienic life with regulation of the various bodily functions, while under treatment for whatever was diagnosed as the illness at that time. The present and probably the third clinical manifestation of the original infection brought on by the periodic dissipation of energy in work and play is at last diagnosed for what it is. Now, just as the first attack and following relapse was "cured," so also could this last one, and with a much better chance of permanence, for the simple reason that now its true nature being known, proper living will often prevent its recurrence. Therefore the treatment of pulmonary tuberculosis as we see it resolves itself into the treatment of its relapses.

Now, while it is impossible to lay down rules to govern every case of pulmonary tuberculosis, yet for purposes of treatment they are best divided into three classes, according to the degree of their resistance, namely: 1. The actively resistant; 2, the passively resistant; and 3, those offering little or no resistance.

Resistance may be approximately measured by the amount of tissue involvement before the patient presents himself for treatment. This will readily explain why one patient will come to us for treatment the first time with extensive lung involvement and even cavity formation, and yet be not much sicker apparently than another one with only slight infiltration at the apices. The difference in tissue destruction as compared with the clinical symptoms is the true index of the individual's resistance to tuberculosis, and forms the logical basis for treatment. Under this scheme a lung involvement of Turban 1, with marked systemic reactions such as daily elevations of temperature, much cough, and expectoration with general weakness, etc., would be classed as passively resistant; and if the condition persists in spite of treatment it would naturally fall in the little or nonresistant class and vice versa.

The treatment of pulmonary tuberculosis in the actively resistant class is very satisfactory. Right here let it be frankly confessed that such patients do well not so much because of the treatment instituted, as because of their great natural resistance to the disease. A good number of these patients, particularly if they are in fair economic circumstances, will do very well right here in the city while attending to their daily affairs. All that is necessary is proper attention to and regulation of diet, elimination, habits, and rest. It is nothing short of mismanagement to send such a patient away among strangers and break up his family, his business, and long established habits of life, merely to carry out what has been dubbed the hygienic dietetic sanatorium treatment, as if a hygienic dietetic régime could only be carried out.
in a sanatorium. These patients will do at least as well if left in the city continuing their accustomed vocations in the midst of their families and friends. Most important of all, the improvement in their nutrition will tend to be much more permanent if the same has been gained while in the city, and of course that is the determining factor in the health of the lung itself.

The writer knows numerous instances where definitely tuberculous patients are attending to daily strenuous affairs, and have been doing so for years, with no demonstrable clinical injury, leading lives useful to themselves, their families, and society by simply observing the cardinal principles of a hygienic life. The prognosis in these cases is excellent. No doubt many of these patients live longer by conserving their vitality, than they might have lived without tuberculosis.

The following from the *Journal of the Outdoor Life*, for June, 1913, in the report of the last annual meeting of the National Association for the Study and Prevention of Tuberculosis, is of interest:

One of the most interesting papers presented at the meeting was that by Dr. Edward C. Brenner, attending physician of the Home Hospital in the East River Homes at Seventy-eighth Street and East River, giving one year’s results of the work of that institution. The Home Hospital was established a little more than a year ago by the New York Association for Improving the Condition of the Poor.

Under the Home Hospital plan, the family unit is preserved, the afflicted family occupying its own apartment in the hospital, and living under the best hygiene conditions. The patients are isolated as far as possible from the well members of the family, and receive the equivalent of sanatorium treatment.

The results obtained with the adult consumptives compare favorably with reports of the leading sanatoria. Sixty-one per cent. have become apparently cured, twenty-two per cent. have had their disease arrested, and eleven per cent. are much improved. And, these astonishing results have been obtained in the very heart of New York City.

The most careful comparison of the cost of the Home Hospital with various country sanatoria, hospitals, and preventoria, reveals the fact that the Home Hospital treatment costs only from forty to fifty per cent. as much as the ordinary methods of treatment. It would seem, therefore, that the opening of the Home Hospital in New York marks an epoch in the practical and humane treatment of tuberculosis among the poor.

The exact scientific explanation that will account for the relative immunity to the patient’s own infection is lacking. Evidently a balance has been struck between the invading organism and the resistance to the same, for physically the patients have just as much lung involvement as ever. It is among this and the next class of the tuberculous (to be described later) that the numerous special treatments, vaccines, sera, and treatments of all kinds that crop up ever so often draw their illustrative cases. The authors of such cases intentionally or willfully ignore the enormous natural resistance on the part of the human body to the tubercle bacillus and deliberately take whatever credit there is to themselves and their special treatments. It is but natural in reviewing the thousands of deaths from tuberculosis, to overlook the countless millions who have been definitely infected and in whom the infection has been overcome absolutely, and entirely maimed, because unsuspected, by both the patient and his medical adviser. A few words of caution before we leave the treatment of this class of patients, and that is that the patient is not to be considered as having struck that balance above mentioned until he has reached and maintained the proper body weight for his age and height as judged by his own standards. Also, that his pulse at rest must be below 80. These together form the most delicate index we have of the amount or lack of tuberculosis intoxication of the body.

Treatment of the passive resistant cases should be directed toward the end of getting them among the actively resistant above mentioned. This class includes all those who show the effects of the toxemia of tuberculosis such as slight daily elevation of temperature, pulse at rest over 80, and digestive disturbances with subnormal weight. Those are the patients who require absolute rest and supervision with the attention that they could get only away from their homes and usual surroundings, preferably in a sanatorium in the country. These are typical examples of an acute exacerbation on a chronic process. The great majority of frankly tuberculous patients as we meet them belong to this class. While on the one hand a small but constant number of them eventually get into the actively resistant class above mentioned, a little larger but equally constant number drift into the little or nonresistant class. A good working prognosis of these passive resistant patients is that fifty per cent. of their number will succumb in five years, of the other fifty per cent. one half or twenty-five per cent. will live for a variable length of time beyond that, despite considerable tissue involvement with occasional relapses, while the last twenty-five per cent. will eventually get into the actively resistant class described above and remain clinically cured.

An open man to man talk with these patients telling them the exact facts and carefully explaining how far their future health lies in their own hands will do wonders toward prolonging their lives; a simple and rational explanation of the cardinal facts of right living, which for them means right working, right eating, right resting, above all clearly impressing on their minds that they have none other than the old fashioned form of tuberculosis or consumption of the lungs. As these people do not as readily imagine themselves to be really tuberculous as they imagine others to be so, it is also well to tell them that they are physically a little below par, and that they must not attempt things they know to be beyond them, and that on account of their condition they will probably for the rest of their lives have a certain amount of cough and expectoration which, beyond exercising the necessary precautions in sanitary disposal, etc. need give them no anxiety, unless they become aggravated to the point of keeping them awake of nights or interfering with meals, etc. It is also well to impress on their minds that while one or several thorough examinations of the chest at first are essential to accurately locate the lesion and measure its extent, further frequent examinations are not only unnecessary but even objectionable, as these only serve to keep the patient unduly keyed up about himself to no purpose, as, unfortunately, the lesion in pul-
monary tuberculosis is not one that the physician can directly antagonize. The patient getting tired of what he looks upon as the wilful inaction of his physician, almost pathetically and quite unconsciously presents himself for examination, more for the purpose of offering the doctor a chance to do something for him, if something can be done, than for any other reason. Furthermore, once the lesion is properly diagnosed the best means of determining the patient’s condition is by a careful observation of his clinical symptoms, particularly his digestive and assimilative functions as evidenced by his weight. Right here it would not be out of place to warn against waiting for a rise of temperature before considering the patient’s condition as having relapsed. Elevation of temperature is not an early sign. It is one of the active symptoms of the system cornered and fighting for its existence, in which, however, it is not as often successful as it might be.

The majority of the passively resistant class do very well on the classical treatment of fresh air, good food in plenty, and rest as the best means of improving their nutrition; once their acute symptoms have subsided, moderate exercise is to be instituted, being gradually increased with the patient’s tolerance, as shown by his general nutrition, temperature, and pulse. After these latter have remained normal for a time (not less than six months), the patient may cautiously try to return to his former work and environment. Very often one will find an initial gain in weight on return of the patient to his former life, a most hopeful sign, sometimes there will be a slight drop in weight at first, only to be regained in a few weeks.

The third class, or those with little or no resistance, as manifested by acute symptoms of the disease that does not subside under the continued rest treatment. These must stay under the most favorable surroundings indefinitely, so as to offer the best chance of recovery to the few who are certain to improve and even be clinically cured in time. An institution in the country offers the best solution of the problem of their disposal. Let it be well understood, however, that they are by no means hopeless. While miracles occur in the course of every disease, they are apparently least frequent in pulmonary tuberculosis. But the rational place for this class is the tuberculosis hospital, where they could receive the attention so necessary to their comfort, and at the same time be removed as a source of infection from the rest of the community.

A MODIFIED DRAINAGE FOR SUPERAPUBIC PROSTATECTOMY.

By George H. Day, M.D.,
Louisville, Ky.

Given a perfect system of drainage in suprapubic prostatectomy, could we reduce the mortality to that of the perineal?

The pendulum of opinion regarding the perineal and suprapubic is swinging, I think, toward the latter—many disciples of the perineal method are now devoted advocates of the suprapubic operation. It is not my desire to advance arguments in defense of the suprapubic. However, to more intelligently discuss suprapubic drainage I must call attention to one point in the anatomy of the prostate and its annexa. The prostate lies at the base of the bladder upon the triangular ligament and above the aponeurosis of Denonvilliers. The traumatism resulting from the suprapubic operation is reduced to the minimum as compared with that of the perineal, and so the destructive anatomical changes resulting are not to be compared, as the traumatism of the suprapubic is limited to the abdomen, bladder, and prostate. The greatest argument in favor of the perineal route has been that of drainage, and the greatest argument against the suprapubic, I believe, is also that of drainage. Then, if we have a perfect suprapubic drainage—one that can be depended upon at all times to drain—would it not be possible to lower the mortality to that of the perineal?

In Freyer’s reports he enumerates cases by the hundred, describing his operation most minutely, going extensively into the pathology of the gland; but describes no method of drainage aside from that of a goose neck shaped glass tubing to fit into a short heavy drainage tube, and this at all times in my hands has failed to drain. Hereetofore the drainage in suprapubic cystotomy resulted in packing heavy layers of absorbent cotton over the abdomen, and allowing the cotton to absorb the overflow—the patient literally floating in his own urine and naturally being anything but comfortable.

Several years ago Dawborn introduced a method of siphonage which was the first step in the direction of suprapubic drainage. I have since modified his idea, and for the past four years have had the pleasure of using a system which settles in my mind the very unsatisfactory question of bladder drainage. Numbers of operators have from time to time introduced methods of siphonage, but all were impracticable in my hands because the abdominal end of the tubing of the Dawborn system and others, placed in the bladder cavity, because of the fluid passing down the long arm of the “Y” causes a vacuum. The tubing in the bladder is drawn and twisted about by this vacuum, and the distal end is drawn to the walls or base of the bladder, occluding completely the lumen of the tube—naturally no drainage. Then it was suggested that a glass irrigating nozzle be introduced into the cavity. This procedure had the same fault as the Dawborn plain tube, the bladder tissues always being drawn and occluding the end of the tube.

Adopting the Dawborn system partially, I next introduced into the abdominal cavity the ordinary Marion tube, four inches long, one inch in diameter. This tube is heavy and non-collapsible, and in the vesicle end has two large eyes for the passage of clots and urine. To the outer portion is fixed a small rubber catheter passing from end to end, through which we can pass the different irrigating solutions. At the external opening we have a perforated stopper with a larger centre opening, through which the Dawborn irrigating tube passes. We then have the Marion tube acting as a caisson, the bladder contents passing through the end and
eyes of the stationary tube and being withdrawn through the smaller or inner tube without the lumen of this inner tube being interfered with at all by the vacuum. The siphonage is regulated so that the bladder contents are drawn off as fast as they accumulate.

We now have water passing from 10, through 8, 7, 11, into 12, causing a vacuum in 6, and withdrawing the bladder contents through 4, 5, and 6, into 11 and 12.

We have used Marion tubes of different diameters, the larger being \( \frac{1}{2} \) inches, the smaller \( \frac{3}{4} \) inch. If city water is obtainable in the patient's room, figure 8 can be connected to the faucet. Then we dispense with the necessity of refilling the irrigator (10), and we have a continuous stream of water passing through 8, 7, 11, and into 12, or, better still, back to the wash stand to be carried off as waste water, the water passing through 8, 7, and 11 of course does not at any time touch the patient and need not be sterile—we simply depend upon this water for our vacuum.

If bladder irrigation or continuous irrigation is desired, the irrigator can be attached to 1, irrigating fluid passing through 1 into the bladder and withdrawn as rapidly as desired through 4, 5, and 6. All that is necessary is to regulate properly 9, and the drainage is continued indefinitely.

THE PAUL JONES.

A CASE OF ARTIFICIAL PNEUMOTHORAX IN THE TREATMENT OF PLEURISY WITH EFFUSION.

By Robert M. Alexander, M.D.,
Wernersville, Pa.

E.F., female, aged twenty-eight years, was admitted to the medical service of Dr. L. Napoleon Boston in the Philadelphia General Hospital, September 11, 1912. The chief complaints upon admission were general weakness, pain in back, distended abdomen, and dyspnea.

**Family History:** There was no history of cardiac, renal, specific, nor malignant disease, nor of tuberculosis.

**Past Medical History:** Patient had the usual acute diseases of childhood, also typhoid fever and diphtheria.

**Social History:** Married; occupation housework. Nursed her mother in law in her last illness, who died of pulmonary tuberculosis two years previous to patient's admission to the hospital. Two sisters in law had also died of tuberculosis in the same house where the patient lived until her present illness. The patient used no tea, coffee, alcohol nor tobacco. Her present illness began three months ago by a swelling of the abdomen; later, she suffered from dyspnea, pain in back, and slight cough, accompanied by general weakness and a rapid, progressive loss of flesh.

**Thermic Features:** The temperature upon admission was found to be 99°F., and three hours later it rose to 101°F. Pulse was 110. The respirations were 30.

**Physical Examination.** The patient was a white woman, rather poorly nourished and anaemic, with no apparent enlargement of the superficial glands. The pulse was rapid (110 to 120), regular, soft, and compressible. The tionsils were small and congested. The pharynx was congested. Anteriorly, the chest was flat, the right apex not showing normal expansion; there was an apparent bulging of the interspaces of the right side. The apex of the heart was displaced toward the left, as far as the midaxillary line. Palpation showed an absence of vocal fremitus below the third rib on the right side anteriorly, and below the angles of the scapula posteriorly. On percussion, flatness was obtained over the right lung below the angle of the scapula posteriorly, and below the third rib anteriorly. Percussion over the portion of the right lung above the third rib, and in the intraclavicular and supraclavicular spaces, gave an overresonant note, or Skodaian tympany. Overresonance was also noted over the greater portion of the left lung. On auscultation, exaggerated breathing was heard over the right half of the chest above the level of the third rib, and the respiratory murmur accompanied by fine rales. To the right of the spine, and on a level with the third rib anteriorly, the breathing was decidedly harsh, and usually accompanied by fine rales. Over the surface of the chest below the third rib anteriorly there was a total absence of breathing. Vocal fremitus was absent over this area, and there was also an absence of the spoken voice sounds. At the upper level of the flattened anteriorly egophony was fairly distinct, and was equally well heard at a point on the same level as the scapula. Percussion over the left lung was moderately exaggerated, due to compensatory emphysema, but at no time was there any evidence of disease of the left lung. The heart sounds, in addition to being rather rapid, suggested an appreciable diminution in muscle tone, and the second pulmonic sound was decidedly accentuated. A physical examination of the abdomen revealed the classic signs of ascites. There was no evidence of disease of the pelvic organs.

**Laboratory Examination:** The blood showed evidence of secondary anemia, without leucocytosis. The urine examination was negative for sugar and albumin. The von Pirquet tuberculin reaction was fairly positive.

**Treatment:** One day after admission the right pleural cavity was aspirated, and six pints of straw colored fluid removed. Two days after this operation the peritoneal sac was aspirated, and six quarts of clear, straw colored fluid were withdrawn. Almost immediately following the removal of the fluid from the right pleural cavity there was a decided improvement, which necessitated its second withdrawal at a second sitting; five and one half pints were withdrawn. In all, the chest was aspirated five times at intervals of from seven to fourteen days. At the suggestion of Dr. Boston at the last three times an artificial pneumothorax was produced, when it was found that the
amount of fluid was greatly lessened. Air was introduced by using the aspirating needle in the chest with a thumb held over it. Three or four deep breaths were taken with the thumb removed from distal end of needle, and the needle was then removed. With the needle in the chest wall, air could be heard passing into the pleural cavity. All the physical signs of pneumonia were soon gone.

The patient was so much benefited by this procedure that I decided to try the same method in the peritoneal cavity. At the second tapping, after the fluid had been removed, the cannula remaining in the abdominal wall, the tissues of the abdominal wall were grasped, and lifted up. Air could be heard rushing in. When the cannula had been withdrawn the abdomen was gently massaged, so that the air could penetrate, as far as possible, all the abdominal cavities. Tympany over the liver showed the presence of air in the peritoneal cavity. This procedure was practised on two occasions. The amount of fluid was markedly diminished at subsequent takings. The fluid from both cavities showed a large number of lymphocytes and a few endothelial cells. No microorganisms were found. The fluid had a specific gravity of 1.020; albumin 4.77 per cent. The peritoneal cavity of a rabbit was injected with five cubic centimetres of the fluid from the patient's peritoneal cavity, and the rabbit did not live.

X ray examinations by Doctor Manges before aspiration showed no evidence of consolidation in the lung, but did show dense adhesions in the right pleural cavity and a dislocation of the heart to the left.

The patient improved under treatment, and went home after being in the hospital two months and five days. She returned for further fluoroscopic examination, nineteen days after her discharge. A pint of dark straw colored fluid was removed from the right pleural and peritoneal cavities, and two days later she was discharged. I saw her seven weeks later, and was unable to detect the presence of fluid in either her pleural or peritoneal cavity. She was able to do her Christmas shopping and later began housekeeping, not requiring a maid to assist her. Soon, however, a cough developed, and eleven weeks after I last saw her, she died in the County Hospital at West Chester, Pa., after the removal of eight quarts of fluid from her abdominal cavity.

A CASE OF MEASLES COMPLICATING PREGNANCY.*

By Samuel J. Scadron, M.D.,
New York,
Adjunct Attending Surgeon, Jewish Maternity Hospital.

The occurrence of measles during pregnancy and the puerperium is of sufficient rarity to warrant my reporting this case.

Case. Mrs. R., aged twenty-five years, primipara, pregnant seven and a half months. Family history was negative. Past history: She had had no serious illness, never had had measles nor any other disease of childhood.

Present history: In March, 1912, the patient contracted a feverish cold accompanied by catarrhal symptoms of the respiratory tract—coryza, sneezing, cough, and headache. These symptoms increased in severity, and on March 11th, she was obliged to take to bed and summon a physician; she then had fever, marked headache, cough, redness of the eyelids, photophobia, and reddish blotches on the cheeks and forehead; the fever continued and the symptoms became aggravated.

On March 13th, she began to have abdominal pains, and on examination I found her in active labor; the cervix was sufficiently dilated and the 2d, 3d, and 4th fingers, vertex presenting, membranes intact; her entire body was covered with a reddish blotchy rash, and she presented all the other typical symptoms of measles; temperature was 103 F., and the pulse was 110. She continued in active labor, and within two hours was delivered of a three and a half pounds child, soon followed by the placenta. The child was perfectly normal and had no rash. One hour after labor the patient was in good condition. The temperature fell to 100° F., and the pulse to 90. The uterus was well contracted although I did not administer ergot. The puerperium was uncomplicated and I discharged her on the twelfth day in good condition, except for a mild conjunctivitis and a slight bronchial cough. The child was normal, nursed during the entire puerperium, and gained eight ounces.

On March 24th, I was asked to see a niece of the patient, six years old, who lived in the same house and was ill. I found her with a febrile cold, bronchitis, and Koplik's spots. Within twenty-four hours a rash developed over the face and the entire body. This child unquestionably contracted the measles from the aunt.

This case is interesting from both the standpoint of the mother and that of the child. As regards the mother, this complication rarely attacks pregnant women and when it does it usually interrupts the pregnancy. In nine out of the eleven cases of measles occurring during pregnancy, reported by Klotz, there was a premature expulsion of the fetus. Some authorities consider this a very dangerous complication, as it predisposes the patient to post partum hemorrhage and pneumonia.

Hulbert reported two fatal cases. (St. Louis Courier and Medical Journal, XVII, 1887, p. 549.) The first patient died on the third day after delivery, and the second patient died on the tenth day post partum. The autopsy on the first patient, two hours after death, revealed the following: No evidence of inflammatory condition of the pelvic organs. The abdominal viscera were congested; the lungs were normal. The heart was arrested in systole. In the left ventricle, intimately interwoven among the chordae tendineae, was found a blood clot. It was fibrin and blood mixed, mostly fibrin, or a clot that had been some hours in forming, which formation progressed slowly and steadily. Nothing was found in the veins leading to or from the heart, but fluid blood.

Jardin reported two cases of measles in the puerperium, and in both cases the attacks were mild, and the patients made an uneventful recovery. (Transactions of the Obstetrical and Gynecological Society, 1900-1902.)

As regards the child: Cases have been reported where the fetus had been affected in utero and showed signs within a few hours of birth. A case of M. Campbell is interesting. (British Medical Journal, February 10, 1903): Mother exposed January 28, 1903; on February 1st, normal labor; on February 9th, patient had a rise of temperature with catarrhal symptoms; on February 11th, rash developed; on February 15th, child became ill; and on February 17th, rash on child. Another boy of the same mother was exposed at the same time, that is January 28th. The mother, however, had had a previous attack. The symptoms manifested themselves twenty-four hours earlier in the healthy boy. The attack was more severe in the boy than in the puerperal woman. The attack was least severe in the case of the fourteen day infant. In my case, although the infant was exposed especially during nursing periods, the child did not contract the disease.

This case was referred to me through the kindness of Dr. A. J. Rongy.

247 East Broadway.
Therapeutic Notes.

Salicylate of Iron in Erysipelas and Other Affections.—M. C. S. Lawrance, in the Practitioner for March, 1913, describes the uses of a preparation made by adding to a solution of sodium salicylate and potassium bicarbonate in equal amounts the British Pharmaceutical Codex liquor ferri perchlorid. For adults the dose generally consists of 7½ grains (0.48 gramme) of the salicylate and the bicarbonate, and 7½ minims (0.46 c. c.) of the iron solution. The latter corresponds approximately to four minims (0.24 c. c.) of the liquor ferri chlorid, United States Pharmacopoeia. The resulting violet colored solution is quite palatable, though, of course, it may be sweetened if necessary. It does not depress or constipate and possesses a well marked antipyretic and sometimes a diaphoretic action.

In erysipelas the author has found the preparation much more effective than any other remedy tried. The disease never lasts more than ten days, and in most instances is cured in three or four days. All pain is relieved. No deaths occurred among the cases in which it was used. With the patient in bed and on a liquid diet, the author applies warm compresses of oatmeal water to affected area, aseptically punctures and drains the blubs should these form, and administers the salicylate of iron preparation every three hours. The treatment should be commenced with a purgative, such as calomel. Where there is well marked delirium, trional is used. When the symptoms abate the salicylate of iron is given at longer intervals and later discontinued. With these measures the temperature becomes, as a rule, normal in twenty-four hours, the disease has ceased to spread, and the patient feels better and is often hungry; solid food is not allowed, however, for the first three days. In cases of great severity the author often adds twice the usual amount of iron to the salicylate solution, thus producing a preparation which is stronger in its action on the disease.

The solution recommended is also remarkably effective in some cases of acute tonsillitis—probably those wholly or partly of streptococcal origin. If, after giving it for three days, there is no marked improvement, it is not worth while continuing with the preparation. Potassium chlorate may be combined with it.

In some cases of cellulitis the iron salicylate solution, used as an adjunct to the ordinary surgical procedures, appeared to do good.

Treatment of Inoperable Cancer or Recurrences.—Robert Knox, in the Proceedings of the Royal Society of Medicine for March, 1913, states that in slowly growing inoperable cancer he has employed energetic x ray treatment with satisfactory results. The method described may also be used in recurrences of considerable size. The area of healthy tissue is protected by thick lead screens. A circular area is cut out of the screen, exposing the tumor and a margin of healthy tissue. Pastille doses of x rays are given, at first unfiltered, later filtered through one millimetre of aluminum, three times a week for several weeks. A marked reaction results and the tumor contracts. In one instance radium exposures were made over the central portion of the growth, fifty milligrammes in a filter of 2.50 millimetres of platinum were applied for six hours. The whole of the new growth was ulcerated, leaving healthy tissue behind. The resulting ulcer slowly healed, and a sound scar was obtained after about three months’ treatment. This intensive form of treatment is well worth a trial in cases which do not yield to any other measures.

Electrical Operative Treatment of Small Simple Tumors.—W. Knowsley Sibley, in the Practitioner for March, 1913, points out the utility of electrolysis in the treatment of small superficial lesions such as sebaceous cysts. If the cyst is small, e.g., of the size of a pea or bean, a negative aluminum needle is inserted into its centre and a current of about five milliamperes is applied and continued for one or two minutes, after which the strength is gradually reduced to zero, and the needle withdrawn. No surgical dressings are required. In a few days the whole tumor will have shrunk, and as the cyst wall has been destroyed by the current, it will not recur.

For larger cysts, a few drops of normal saline solution are injected into the centre of the tumor, and both positive and negative needles, made of copper, are then inserted into the centre of the cyst by separate openings, but fairly close together and parallel. A current of from two to five milliamperes is then turned on for from three to five minutes, according to the size of the cyst. Copper salt is rapidly deposited on and about the positive needle, and there may even be difficulty in withdrawing it unless the current is reversed for a few seconds before the operation is completed. Both needles having been withdrawn, the punctures are closed with a drop of collodion. In from four days to a week, the opening through which the negative needle was inserted will have enlarged and joined the other, and if a sufficient amount of current has been used, it will be found easy to enucleate through this opening the whole of the cyst contents together with the cyst wall; or, the contents may have escaped, of themselves, as a congealed necrotic mass. The loose skin over the cyst soon contracts, and little evidence of the previous tumor formation remains.

The tumors formed by Molluscum contagiosum are cured by the same process.

The operation can be rendered painless by the local hypodermatic injection of a two per cent. novocaine solution.

Ganglions are cured by inserting the negative aluminum needle into their centres, and using a current of from five to ten milliamperes for from one to five minutes. The treatment may be repeated in a week, if necessary.

Telangiectases are readily contracted and obliterated by the insertion of the negative aluminum needle for a few seconds: freckles and other pigmented deposits may be dealt with efficiently in the same way.

Boils and carbuncles may be treated by puncture with a zinc electrolysis needle.
Suggestive in this connection are the remarks of Professor Benson at the recent International Congress, and which fortunately have been widely disseminated through the lay press: "I should be sorry," said this distinguished investigator, "to see adopted the violent methods put to use in some parts of the United States. It is one thing to check the reproduction of hopeless defectives, but another to organize wholesale tampering with the structure of the population, such as will follow if any marriage not regarded by officials as eugenic is liable to prohibition. Nothing yet ascertained by genetic science justifies such a course, and we may well wonder how genius and the arts will fare in a community constructed according to the ideas of such legislators as we are told propose this measure in Pennsylvania and New Jersey, to which we might add several other States. Legislative tyranny and its handmaiden, brutality, are increasingly holding sway under the guise of applied eugenics.

The outlook is not a promising one. As a result of misdirected—though well meant—laws, a large proportion of our younger population will be reduced, as far as marriage is concerned, to a level approximating that of the leper if, when seeking the holy bonds of matrimony, they answer truthfully all questions concerning their physical condition. But in many instances, they will swear falsely; in others, the truth will be told and marriage prevented or delayed; in others still, carnal union will occur without marriage and common law wives will become as numerous as in those European countries in which official red tape converts legitimate unions into an ordeal. In the end, the true aim of enforced eugenics will have been thwarted: the birth of physically and mentally handicapped children will not have been reduced; they will simply have received the additional brand of illegitimacy.

It is to be hoped that many States will revise their marriage laws in such a manner as to meet the demands of equity to all, while efficiently protecting the innocent, particularly the bride to be and her offspring.

TOXIC AMBLYOPIA FROM TOBACCO ALONE.

Many years ago it was learned that certain drugs were able to cause blindness or at least a great impairment of vision, without producing any changes in the eye that were recognized as such at the time, and the name toxic amblyopia was given to this condition. Modern research has shown that all of these drugs do not produce this effect in the same way, and that certain ones induce a degeneration of a certain bundle of fibres in the optic nerve, known as the papillomacular, which supplies the area of
most distinct vision in the retina, manifested by an abnormal paleness of the temporal side of the optic papilla. Such a degeneration is also met with in multiple sclerosis, sometimes in a bad case of diabetes, or as a result of inflammation of the accessory sinuses, but other symptoms of the disease are always present. Drugs produce it only through chronic intoxication, and of these the combination of alcohol and tobacco is the one most often responsible. It has been asserted rather positively that tobacco alone is unable to produce this condition, but the case reported by Dr. M. L. Foster in the Archives of Ophthalmology for July, indicates strongly that this assertion is incorrect, and that in certain individuals, tobacco unaided by alcohol can produce a toxic amblyopia. His patient was a man 65 years old, who had been a teetotaler for over forty years, had been an inveterate smoker for many years, but had developed no symptoms of multiple sclerosis or of any other disease to which the lesion could be referred, and made an excellent recovery under treatment after he had stopped using tobacco.

The writer emphasizes the difficulty of obtaining absolute proof that any man does not drink, pointing out that this requires incontestable evidence covering every moment of the day and night for a long time, but we are inclined to agree with him that no man could succeed in posing as a total abstainer for forty years in a small community where he was well known, and yet drink alcoholic liquor in sufficient quantity, and with sufficient regularity, to produce a toxic amblyopia. We are obliged to believe that this man succeeded in accomplishing this seeming impossibility, and that he stopped drinking and smoking at the same time, as total abstinence from both alcohol and tobacco are necessary in the treatment of an alcohol-tobacco amblyopia, or that his condition was produced by the tobacco alone. The latter certainly seems the more probable.

We cannot help feeling that this case is unusual, that the deleterious effects of tobacco are not apt to be exhibited in this manner; in short, that this patient had a certain idiosyncrasy, and yet it is possible that we have been accustomed to ascribe too subordinate a position to this drug in the production of this disease. We shall hardly feel quite as secure hereafter in the enjoyment of our pipes and cigars.

THE TREATMENT OF TETANUS.

There can be little question that as a rule the doses of antitetanic serum have heretofore been entirely inadequate especially when given subcutaneously. Of late the tendency has been toward a marked increase in the amount of antitoxine administered in diphtheria, and it would seem that larger doses are even more essential in tetanus. decidedly of this opinion are Dr. A. P. C. Ashhurst and Dr. R. L. John, of Philadelphia, who contribute to the American Journal of the Medical Sciences for July a report of twenty-three cases of this disease. Believing that the first indication in the treatment is the removal of the source of the toxine, the tetanus bacilli, they recommend the open treatment of the wound, with the employment of hydrogen peroxide and a weak solution of iodine, and the avoidance of caustics, which by the formation of sloughs favor the growth of the bacilli. The second indication is to head off and neutralize the toxine already formed through the use of tetanus antitoxine. No matter what the method of injection, the most important thing is to get the maximum amount of antitoxine indicated into the patient’s body at the earliest possible moment. If the injections are given subcutaneously, in immense quantities are required for an adult, with the usual acute type of the disease, at least 100,000 units within the first twenty-four hours. If given intraspinally, from 3,000 to 10,000 units should be given; this need not, as a rule, be repeated in less than eighteen or twenty-four hours. Intraneural injections should be made in as great amounts as the nerves will absorb. The third indication is to depress the functions of the spinal cord. The drugs most often employed for this purpose are chloral, chloroform, and similar products, the bromides, physostigma, hyoscine, morphine, and magnesium sulphate. Finally, the patient, as well as the disease, must be treated. This involves the securing of absolute quiet, the most careful nursing, and the administration of food at all hazards, by a nasal tube if necessary. Saline solution by the bowel tends to overcome the dehydration of the tissues produced by the excessive muscular activity. The excellent results reported in some quarters from the use of phenol injections should not be forgotten, as this is a remedy much more readily obtainable than antitoxine.

An outline of the manner in which Ashhurst and John purpose to treat the next case of tetanus which comes under observation sufficiently early includes the immediate exposure of the motor nerves leading from the wound, as near the cord as practicable, and the injection toward the cord of as much antitoxine as each will contain: an intraspinal injection of at least 3,000 units, and the injection of from 1,500 to 3,000 units deeply into the muscular tissues around the wound. During the first day a moderate amount of antitoxine (perhaps 10,000
INTERNESHIPS FOR WOMEN STUDENTS.

The status of the woman physician and the superior opportunities for women in the medical profession were discussed at the International Medical Congress. Attention was called to the fact that the number of women entering the profession was decreasing. Referring to this fact one esteemed contemporary draws the conclusion that "the existence of unrestricted opportunity for the woman physician signifies very little." Analysis of the question shows, however, that the opportunities for the woman physician are not unrestricted. Besides admission to the larger medical colleges, women are refused internships in hospitals other than for women. As is well known no amount of dispensary work, or years of conscientious clinical observation, will ever compensate for the lack of training in general hospitals.

Women physicians have now advanced as far as perseverance and devotion to duty can carry them. In hospital dispensaries, where only a few years ago they were reluctantly granted the privilege of working, they are to-day sought eagerly—possibly because of their more faithful attendance. The custom of having women physicians fill the posts of examiners and "medical advisers" for women students in the colleges is gaining ground. In the fields of applied hygiene and of research women are proving their worth. Many more instances could be given illustrating the fact that the services of women physicians are being increasingly valued.

However, as long as they will be debarred from general hospitals, i.e., excluded from the competitive hospital examinations, women will be deprived of one half of their medical education; and of a corresponding degree, therefore, of efficiency as practical physicians. An effort to offset this drawback is to be inaugurated, we hear, by one of the Philadelphia medical schools, that of Temple University, in keeping with the new law in Pennsylvania which requires one year of internship before applications for the State license can be filed. Both hospitals—aggregating two hundred beds—of this institution are to be available for its students, regardless of sex. It is to be hoped that other colleges will follow this laudable example.

PATHOGENESIS OF EPILEPSY.

A. Pierret, in the Revue de médecine for July, 1913, assumes as the basis of epilepsy that many subjects afflicted early in their development with infectious diseases involving nervous tissues become abnormally susceptible to disturbance at the seats of subsequent scarring in these nervous tissues. In these cases an intoxication of any kind is capable of bringing on convulsions, which remain of a local nature either at the beginning or the termination of the attacks. The scope of "idiopathic" epilepsy is becoming more and more restricted. The phenomena arising through the operation of toxic influences on cured or slowly progressive scleroses in the nervous system are not alone of convulsive nature; they may be either motor, sensory, or mental, and are often very transitory. This may explain the various evanescent phenomena witnessed in all patients with old sclerotic foci, e.g., cases of general paralysis, tabes, syphilis, etc. Frequently regarded as hysterical, these manifestations have nothing in common with the neurosis, unless the latter be itself of toxic origin, as is probably the case in many instances. Rational treatment of neurosis, then, consists in the utilization of all measures that will tend to eliminate endogenous or exogenous intoxication.

THE VICISSITUDES OF SCROFULA.

A. J. Delcourt, in the New Orleans Medical and Surgical Journal for August, 1913, having passed in review the conflicting opinions prevailing from time to time regarding scrofula, states that we can now at least identify two kinds of scrofulous affections, according to the presence and the predominating influence of the specific bacilli, viz., a tuberculous scrofula and a pyogenic one. Viewed in its broadest aspect, scrofula may be said to represent a clinical drama in which three personages play successively a specific part, but one of which, the Koch bacillus, in the end fills the chief rôle. This drama is in three acts and many scenes, each one corresponding almost exactly to the chronological subdivision assigned by Bazin. The practical conclusion is that we should put a stop to the long and dreadful pathological drama in its first scene, by attacking the cutaneous and mucous lesions, which represent perpetual foci of suppuration, leading to chronic microbic infection; at the same time exercising a constant, vigilant, and preventive care, aided by good hygienic and restorative treatment.

THE MODERN HOSPITAL.

Under the title of Modern Hospital appears this week the first number of a monthly publication whose purpose is signified by the title. It is the hope of the editors, as stated by them, that the "hospital world may find in the new agent a vehicle of expression that will bring into wider usefulness the experience and the learning of each individual, to the end that these may become the common harvest of all."
News Items.

A Pellagra Hospital at Durham, N. C.—Announcement made is that George W. Watts, the donor of Durham Hospital, has presented a large donation for the erection of a pellagra hospital in Durham, provided the United States Government makes that city the southern headquarters for the pellagra investigation. Surgeon General Blunt, of the United States Public Health Service, will go to Durham to make an investigation. Congress recently announced its willingness to spend $50,000 on pellagra investigation, and the towns of Durham and Raleigh have both been suggested for the government station. The Watts Hospital in Durham has pellagra patients, but Mr. Watts has declared his willingness to erect a separate building for their care and treatment.

Child Welfare in Philadelphia.—A new organization, called the Child Federation, has been organized in Philadelphia, to take the place of the Child Hygiene Association, and a charter for the federation will be issued the first week in September, and an active educational campaign inaugurated to preserve the health of the children and develop them mentally and physically. The incorporators and directors of the new association are as follows: President, Edward, and Dr. D. H. Foreman, of Kane; Jesse D. Burks; treasurer, Albert Pepper Gerhard; secretary, Dr. Howard Childs Carpenter; Dr. Charles A. E. Codman, Dr. C. Lincoln Furbush, Dr. P. Claxton Gittings, Dr. H. A. Stewlock Hamill, Dr. Charles J. Hatfield, Dr. Harry D. Jump, Dr. H. Crockett Johnson, Dr. Joseph S. Neff. Beginning on October 15th the federation will conduct five baby shows in different sections of the city.

New Procedure in Relation to Contagious Diseases in New York.—A circular is being prepared by the Department of Health of the City of New York describing the present procedure in the surveillance of diphtheria, scarlet fever, and measles, and will shortly be ready for delivery and distribution by the nurses and inspectors of the department. The number of infections and cases of children suffering from these diseases. In the meantime, in order that physicians, particularly, may take note of the changes in procedure, the circular is printed in the August 16th issue of the Weekly Bulletin. The most noteworthy changes in procedure which are indicated in the new circular are as follows: 1. Insusceptible persons (those who have had diphtheria, measles, or scarlet fever), will not be excluded from school while a case of infectious disease exists at home, provided isolation is being satisfactorily carried out. 2. Cases of measles are terminated five days after the appearance of the rash, provided such a course is warranted by the clinical condition of the case. The circular, as prepared for general distribution, will be printed on the same stock, in English on one side and in either German, Italian, or Yiddish on the other side.

The Pennsylvania Homeopathic Medical Society.—This society, which is one of the oldest members of the American Homeopathic, will hold its annual meeting in Bedford Springs on Tuesday, Wednesday, and Thursday, September 2d, 3d, and 4th. The officers and chairman of the various bureaus are: President, Dr. Harvey L. Nicholson, of Pittsburgh; vice-presidents, Dr. W. M. Feagle, of Hanover, and Dr. D. H. Foreman, of Kane; secretary, Dr. E. H. Pond, of Pittsburgh; treasurer, Dr. Ella D. Goff, of Pittsburgh; necrologist, Dr. W. F. Baker, of Philadelphia; censor, Dr. R. T. White, of Pittsburgh; chairman of medical and medical committee, Dr. Charles Ley, of Pittsburgh; bureau of education, Dr. Dr. Samuel Hamilton, Jr., of Pittsburgh; homeopathic institute and clinical medicine, Dr. S. M. Reinhardt, of Pittsburgh; bureau of surgery, Dr. F. C. Morris, of Pittsburgh; bureau of gynecology, Dr. J. F. Crocker, of Philadelphia; bureau of pathology and pathological anatomy, Dr. J. C. Calhoun, of Pittsburgh; bureau of ophthalmology, otology, and rhinology, Dr. J. B. Bryson, of Pittsburgh; bureau of sanitary science, Dr. Anna Clark, of Scranton; bureau of pedology, Dr. Anna Johnston, of Pittsburgh; chairman of exhibit, Dr. J. D. Kistler, of Pittsburgh; and chairman of entertainment committee, Dr. William Joline Martin, of Pittsburgh.

Personal.—Dr. Henry L. K. Shaw, consulting pediatrician to the New York State Department of Health, represented the department at the English Speaking Conference on the Prevention of Infant Mortality, held recently in London. Dr. J. W. Kerr, assistant surgeon general of the City of New York, has recently closed his large practice, and represented the United States Government at this congress.

Dr. W. A. Bing, bacteriologist in the Division of Laboratory Work of the New York State Department of Health, has been assigned to work in connection with the investigation of the disease at the outbreak of cholera in St. Lawrence, now being undertaken by the international Commission on the sanitary condition of these waterways, with the cooperation of the State Department of Health.

Dr. G. W. Bower, of Norristown, Pa., has been appointed superintendent of the new Schuylkill County Insane Asylum at Pottsville, Pa. Dr. William Gautner, of Philadelphia, has been appointed assistant to Doctor Bower.

Dr. H. T. Summersgill has retired as superintendent of the City Hospital, Cincinnati, and Dr. A. C. Bachmeyer has assumed charge as acting superintendent, pending the appointment of a successor to Doctor Summersgill.

Medical Society of the Missouri Valley.—The twenty-second annual meeting of the Missouri Valley Medical Society will be held at Carthage, Mo., on Thursday and Friday, September 18th and 19th, under the presidency of Dr. H. B. Jennings, of Council Bluffs. The Hotel Home will be headquarters and meeting place for the society. Twenty papers are listed on the programme; arrangements have also been made for the entertainment of the visiting physicians and their friends. Inquiries regarding the meeting should be addressed to Dr. Charles Wood Fassett, St. Joseph, Mo., secretary of the society.

Civil Service Examinations in Philadelphia.—Among the disadvantages of the Civil Service Division of the Bureau of Education is the fact that parents have to pay for the examinations. The Commission will hold examinations in the near future are the following: On September 19th, at 9:30 a.m., an examination for the position of first assistant resident physician, medical service, Department of Public Health and Charities, with a salary of $1,200 a year, with room and board. At the same time an examination will be held for the position of resident assistant physician, in the same service, with a salary of $600 to $900 a year, with room and board. On September 26th, an examination will be held for the position of assistant bacteriologist in the Department of Public Works, with a salary of $1,200. Applications must be executed and filed with the commission not later than the third day prior to examination. All candidates are reminded that no information is as to the requirements for the examinations may be secured upon request to the Commission, Room 875, City Hall, Philadelphia.

Civil Service Examination for Professor of Pharmacology.—The United States Civil Service Commission announces an examination on September 10th, for men only, for the position of professor of pharmacology in the Hygienic Laboratory of the United States Public Health Service, Washington, D. C., at a salary of about $400 a month. The position is to be filled as soon as it is desired to secure the services of a man who has had broad training and extensive practical experience in the various branches of pharmacology, physiology, physiological and pharmaceutical chemistry, chemotherapy, etc., as they relate to the United States Public Health Service, and who is well qualified to undertake work along these lines of a research, cooperative, and supervisory character. Applicants should have had practical experience in the study of chemicals as well as in experimental pharmacology; they should have had some experience in chemical research and be familiar with its methods. An educational training equivalent to that required for the degree of Ph. D. from a university of recognized standing, and not less than ten years' experience in pharmacology and closely allied subjects since leaving the university, are prerequisites for consideration for this position. For further information regarding the scope of the examination, apply to the United States Civil Service Commission, Washington, D. C.
Pith of Progressive Literature.

CORRESPONDENZ-BLATT FÜR SCHWEIZER ÄRZTE.
July 3, 1913.

Treatment with Carbonic Acid Snow.—E. Sommer says that the factors of chief importance in use of carbonic acid snow are: 1. The duration of its application; 2. the pressure with which it is applied; and, 3. the individual sensitiveness, or the power of resistance of the tissues. Hence the treatment may be regulated by controlling the time of exposure and the pressure in order to produce different degrees of reaction. Carbonic acid snow freezes the tissue in from five to ten seconds so as to produce a dermatitis that lasts several days without a blister, crust, or scar. In from ten to fifteen seconds it produces a redness and swelling which becomes covered by a crust in two or three days, which is thrown off in eight or ten days leaving no scar. After twenty seconds a blister is formed which is followed by a crust that is thrown off in one or two weeks. After thirty seconds this condition is more marked, the crusts fall off in from two to three weeks and, if the pressure is sufficient may leave behind rather insignificant scars. An exposure of fifty or sixty seconds produces a large blister with a crust, and generally leaves a smooth, white, lustrous, superficial scar. The reaction lasts three or four weeks or more. The duration of the application varies with the nature of the affection to be treated, and with the age of the patient. The pressure varies with the depth to which the effect is desired. Some pressure is always necessary, as without it there is no freezing. No effect is obtained deeper than three millimetres. The various skin diseases in which it is of use are enumerated.

WIENER KLINISCHE WOCHENSCHRIFT.
July 3, 1913.

Syphilitic and Postsyphilitic Diseases of the Kidney.—Richard Bauer and Paul Habetin say that chronic diseases of the kidney doubtless exist which can be explained only as results of a previous infection with syphilis and present a characteristic clinical picture. It is still uncertain whether the disease is the result of the action of toxines, or of a settlement of spirochaetes in the kidney. The serum reaction is always well marked. Antisyphilitic treatment is of use and is certainly not harmful. Several cases are reported, which illustrate the clinical picture.

The Growth Inhibiting Influence of the Spleen upon the Sarcoma of Rats.—Paul Biach and Oskar Weitmann find that the tissue of the spleen when injected and mixed with the tumor, inhibits the growth of sarcoma in rats. A spleen from a sarcomatous animal exhibits a much stronger inhibitive power than one from a normal animal. This power of inhibition seems to depend on an increase of the natural inhibition and upon the presence of specific substances that are destructive to the tumor cells.

July 10, 1913.

Experimental Studies of the Delayed Pulse.—Edmund Hoke and Julius Rihl find this pheno-

PITH OF PROGRESSIVE LITERATURE.

non not increased by compression of the arch of the aorta for an hour, increased by section of the pulmonary nerve, diminished by small doses of digitalis and epinephrin, but increased by large doses of the same drugs, increased by stimulation of the vagus, diminished by stimulation of the accelerating nerves of the heart.

Biliary Peritonitis.—Robert Vogel believes that biliary peritonitis is always due to perforation, although this is not always easily found.

LYON MÉDICAL.
July 7, 1913.

Embolism of the Anterior Coronary Artery.—L. Gallavardin and P. Dufourt report a case in which this condition was discovered at the autopsy, and refer to three others previously reported in the literature. In each, the cause of the embolism was the detachment of endocardial vegetations, or of clots, at the ventricular apex. Coronary embolism should be thought of where, in a patient succumbing rapidly, apparently to some cardiac disturbance, there coexists, along with precordial pain, anxiety and progressive collapse, marked bradycardia of sudden advent. This bradycardia may be due to obliteration of the circumflex branch, which can occur more readily through embolism than through thrombosis. Since embolism of the anterior coronary induces death before cardiac infarction can have become established, there is nothing to suggest the propriety of examination of the coronaries at autopsy. From the medicolegal standpoint especially, it is of importance that the coronaries be opened in all cases of sudden or rapid death, even in the absence of fibrous plaques or of recent infarction of the myocardium.

PARIS MÉDICAL.
July 14, 1913.

Chronic Parenchymatous Nephritis of Tuberculous Origin.—Léon Bernard asserts and deduces clinical evidence to the effect, that tuberculosis, e. g., of the lungs, is frequently a cause of chronic parenchymatous nephritis. The lesions produced do not include tubercles. Amyloid change may or may not coexist.

Dose of Salvarsan.—G. Milian refers to the fact that most of the instances of the serious untoward effects of salvarsan have occurred where 0.6 gramme of the compound had been given. In patients who have already taken arsenic in other forms, Milian gives four doses of 0.3, 0.4, 0.5, and 0.6 gramme, respectively, at six day intervals, while in those who have never taken it, he begins with only 0.2 gramme, then continues with 0.3, etc., as in the preceding. About ten per cent. of radical cures can be obtained with this method. The course of salvarsan should be followed, however, by intramuscular injections of 0.05 to 0.01 gramme of calomel, four to six times weekly for six weeks: this to be followed, in turn, by twenty days of combined mercury bismuth and potassium iodide internal medication. Then, after ten days’ rest, Milian advises twenty successive daily intravenous injections of mercury cyanide in the dose of 0.01 to 0.02 gramme. Finally, another series of salvarsan injections should be given.
PRESSE MÉDICALE.
July 26, 1912.

Pituitary Medication as an Intestinal Excitant.
B. A. Houssay and J. Beruti maintain that fluid
pituitary preparations constitute the most efficient
agent now available for bringing about intestinal
contractions. That this fact has not as yet been
generally recognized is because insufficient doses have
been used. The dose given for the purpose men-
tioned should be larger than that used as an oxy-
tocic. Three c.c. of a twenty per cent. extract of
fresh posterior lobe from the ox is the proper dose
for adults, and will induce defecation in eighty-
eight per cent. of all cases. Within two or three
minutes after the subcutaneous injection of the rem-
edy the patient becomes conscious of intestinal
movements and almost always, within six to sixty
minutes, evacuation follows. Slight pain is often
experienced; pallor is also a customary symptom,
and the pulse rate increases. The bowel movement
may recur on the day of the injection and frequently
it remains satisfactory on the succeeding day or
two. In fecal impaction the drug may be given in
conjunction with mechanical treatment and enemas.
In addition to its use as a prophylactic and curative
agent in postoperative intestinal paralyses, pituitary
extract permits of the use of morphine in cases
where its employment would otherwise be unjustifi-
able, counteracting the paralyzing effect of morphine
on the intestine and preventing meteorism. In peri-
tonitis the favorable effect of the extract on the
intestinal and general circulations and its diuretic
action are also of value. A tonic effect on the bowel
can be secured by continued use. Small hypodermic
doses stimulate gastric motility and increase the flow
of gastric juice. Administration by mouth, even in
large doses, does not afford results comparable with
those already mentioned, and does not appear to be
indicated at any time.

July 30, 1912.

Impaired Resonance over the Right Lower
Thorax as a Sign of Typhoid Fever.—C. Lesieur
and J. Marchand found this sign, first described in
1911 by the former author, positive in eighty-seven
out of 114 cases of typhoid fever. Many of the re-
mainning twenty-seven cases were already about to
convalesce, while in others additional signs showed
that the lung was diseased and therefore probably
responsible for the impairment of resonance. Among
seventeen cases of benign typhoid fever, the sign
was positive in nine instances, while in various non-
typhoid conditions, it was only rarely present. Be-
sides its evident diagnostic value, the sign is of use
from the standpoint of prognosis, as its reappearance
or persistence after the temperature has fallen
betokens a relapse, thus suggesting caution in the
diet and administration of hexamethyleneamine.
The impaired resonance at the right base is generally
to be explained as the result of hepatic enlargement.

REVUE DE CHIRURGIE.
July, 1912.

Treatment of Pott's Disease.—F. V. Albee de-
scribes in full his method of correcting the de-
formity in this affection and causing the tuberculous
process to subside by grafting a piece of the tibia
on the posterior aspect of the spinal column. The
paper is based on a series of fifty-five cases, operated
in with uniformly gratifying results. Albee's pro-
cedure was discussed in this JOURNAL for March 9,
1912, p. 450.

Treatment of Fracture of the Petrous Bone.—
H. Nimiier and A. Nimiier adduce evidence to the
effect that in the vast majority of skull fractures in-
volving the petrous portion of the temporal bone the
tympanic cavity is primarily in an aseptic state, and
advise against operative intervention or strenuous
attempts at disinfestation of the auditory passages in
cases of fracture with hemorrhage from the ear, lest
infection be, on the contrary, introduced with the
fluids used. Merely an absorbent dressing should be
applied to the external ear, with perhaps a wick of
gauze inserted in the meatus to assist the drain-
age of blood to the external dressing where hemor-
rhage is profuse. Dirt seen in the meatus should
merely be wiped off with fine tampons of cotton on
an applicator. Hydrogen dioxide or boracic acid
should not be used. When the hemorrhage ceases,
the drying of the clots insures their being in an
aseptic condition. A few drops of a one in twenty
solution of phenol in glycerin might then be placed
in the ear, and of a one in forty solution of menthol
in oil, in the nasal cavities; hexamethyleneamine
also can be prescribed in doses of 0.5 gramme four
or five times a day. In cases of petrous fracture in
persons suffering from chronic otitis media, or
where this complication appears after the fracture,
neither routine abstention from operation, nor regu-
lar intervention, should be made a definite rule, but
the case should be managed according to other indi-
cations, prompt and complete operation being neces-
sary, for instance, when a focus of osteitis has de-
veloped in the depth of the traumatized petrous
bone. Repeated lumbar puncture is indicated both
for diagnostic and therapeutic purposes in cases
where infection is feared. In the presence of an ex-
tradural hematoma complicating petrous fracture, it
should be exposed and removed through the masti-
dow. Where there are, on the other hand, signs of
an intradural hematoma, which repeated lumbar
punctures fail to dispel, the supramastoid portion of
the temporal should be opened, incision of the dura
in this region permitting exploration of the dorsal
aspect of the pyramid, if required.

Metastatic Brain Abscess Related to Suppara-
tive Processes of the Liver and Lungs.—Con-
tead reports three new cases of brain abscess fol-
lowing amebic dysentery and discusses fifteen cases
collected in the literature. Abscesses of this class
run a slow, uneventful course, like "cold abscesses." In
one of the author's cases brain symptoms did not
appear until ten months after an operated hepatic
abscess had healed; usually the interval is two or
three months. The infective agent causing the ab-
scesses may be either one of the ordinary pyogenic
organisms or the dysenteric ameba. In spite of the
medicor results hitherto obtained, exposure of the
abscess is indicated in these cases, provided localiza-
tion is possible. Subcutaneous injections of emetine
should be administered from the beginning of the
treatment.

Untoward Effects of Unilateral Section of the
Internal Jugular and Pneumogastric.—Paul Gui-
bal reports the case of a man who, six hours after
the termination of a radical operation for laryngeal cancer, in the course of which the left vagus nerve and internal jugular vein had been cut, showed physical signs demonstrating solidification of the inferior half of the left lung, together with rapid breathing, tachycardia, and fever. Right sided hemiplegia gradually supervened, and the patient remained in a deep stupor until death took place, less than forty-eight hours after the operation. The pulmonary lesion is considered by the author to have been an instance of vagal pneumonia, such as is frequently observed to occur in experimental work after vagus section and also sometimes in man after traumatic—not surgical—section of the nerve. The brain disturbances are ascribed to the section of the vein, nothing else having been done during the operation that could have influenced the intracranial circulation. Although no autopsy could be performed, cases from the literature are cited to illustrate the fact that where there is a difference in size between the jugulars of the two sides, ligation of the larger vessel may lead to untoward results. It is not possible to ascertain by incision and examination of the cervical portions of the jugulars whether one can be ligated without danger, for Rohrbach has shown that the deep portion of a jugular, adjoining the bulb, and the corresponding lateral sinus, may be aplastic in spite of the fact that the cervical portion is of normal size. Unilateral jugular ligation is thus not devoid of risk, and should be practised only where it is absolutely necessary.

REVUE DE MÉDECINE.
July, 1913.
Eruptions Due to Secondary Infection Occurring during the Course of Measles.—E. Weill and C. Gardère report eight cases of diffuse eruption due to secondary infection in the measles patients of a certain hospital ward. Four rapidly terminated in death. In five the eruptions were scarlatinoid, and these cases occurred in close succession during a period of unusual overcrowding in the ward. Simultaneously, the general mortality from measles rose and septic complications became more frequent. In another patient the eruption was papulopustular, and in the two remaining cases comprised in the series of eight, a typical erythema nodosum was observed. The blood culture was positive in these three cases, the streptococcus being found in one, and a staphylococcus in two. Discussing the secondary eruptions during measles in general, the authors point out that they appear first symmetrically over the limbs, especially at the wrists, ankles, elbows, knees, and upper portions of the buttocks, then spread to the remaining areas over the limbs or even to the trunk. There is no itching. The mucous membranes are not involved, except in grave cases, when infected ulcers are seen in the mouth and pharynx. The eruption persists only from one to five days, and desquamation is incomplete, though frequent in the scarlatinoid eritema. On the whole, the prognosis in these cases is grave. Collected statistics show forty-one deaths among seventy-five patients—a death rate of fifty-four per cent. Typical scarlatina can easily be differentiated from the scarlatinoid eruption, but since the symptomatology of the former is subject to many variations, difficulty may be experienced. As an aid to diagnosis, the blood examination appears of most importance. In the author's cases the degree of polymorphonuclear leucocytosis was inferior to that of true scarlet fever; more characteristic, however, of the scarlatinoid rashes was a distinct increase in the mononuclears and decrease in the lymphocytes. Suppurative conditions in the nose, mouth, and lower respiratory passages invariably accompany the eruptions in question. The treatment of the rashes is largely prophylactic, and consists in care to avoid overcrowding of wards and providing proper ventilation and attendance.

Sensitization of the System by a Fungus of Pulmonary Origin.—L. Jannin reports the case of a man aged twenty-nine who suffered from what clinically appeared to be pulmonary tuberculosis, with successive acute exacerbations, but with preservation of a fairly good general condition, and fever rarely exceeding 37° C. The patient had been troubled with abundant expectoration since childhood, and at the time of examination, ejected every morning one or two tumblerfuls of mucopurulent sputum. The fungus known as Mycoderma pulmonem was always found in copious amount in the sputum, even when the patient's diet was so modified as not to favor the development of the parasite and the mouth and pharynx carefully disinfected. The spores of the fungus were agglutinated by the patient's serum, and intracutaneous injection of soluble toxines from it caused a pronounced general as well as a local reaction, showing that the body had become sensitized to the parasite. In spite of the evident derivation of the fungus from the bronchi or lungs in this case, the author holds that in most instances the mycoderma, when found in the sputum (especially in cases of tuberculosis) is not derived from the lungs. The repeated finding of a few tubercle bacilli in the sputum of the author's case prevents him from ascribing the lung cavities noted to the mycoderma. The case permits, however, of classing the fungus in question among the possible microphytic associations of tuberculosis. The development of the fungus in cavities formed through the agency of the tubercle bacillus appears to have imparted special characteristics and a special course to the morbid process present.

ROUSKSY VRATCH.
May 11, 1913.
Experimental Cultivation of Leucocytes from Leucemic Blood.—P. P. Avroff and A. D. Timofeevsky cultivated leucocytes from leucemic blood, according to Carrel's method. They found that young leucocytes were capable of energetic multiplication, and by further development might be transformed into giant cells and microphages.

Headaches Caused by Lowering of Intracerebral Pressure.—S. D. Tladytychko cites experiments on animals and clinical cases, from other sources as well as his own, to prove that the lowering of intracranial pressure may cause persistent headaches. These are characterized by their constancy and resistance to ordinary therapeutic agents. They occur after a profound emotion of a negative
character, are not caused by defective vision, are not accompanied by increased intraocular pressure, and are relieved only by such measures as eserine, sclerotomy, etc. He explains their origin by the supposition that the change of intracranial circulation changes the normal position of the optic disc and retina, thus acting reflexly on the cranial nerves.

**Bacteriolysins in Woman's Milk.**—P. S. Medovikoff established experimentally the presence of bacteriolysins in mothers' milk, and assuming that these are absorbed by the nursing child, he explains the greater resistance of breastfed babies to infection.

**Abderhalden's Reaction of Pregnancy.**—P. G. Lurje applied the Abderhalden serum test in eighty-four cases, of which forty-seven were of pregnant women, seventeen nonpregnant and eighteen newborn, the blood from the latter being obtained from the umbilicus. In the pregnant women a positive test was obtained in every case. Of the seventeen nonpregnant persons eleven gave a negative and six a positive reaction. Of the latter was one healthy man, one healthy woman on whom a hysterectomy was performed nine years previous, two women with disease of the annexa, one woman with a fibroid, and one with cancer of the uterus. The reaction was also negative in two cases of extrauterine pregnancy. These results show that the Abderhalden reaction is not strictly specific, a conclusion reached by other authors.

*May 18, 1913.*

**The Various Phases of the Action of Strychnine on the Isolated Heart of Warm Blooded and Cold Blooded Animals.**—A. A. Tetjeff experimented with strychnine on the isolated hearts of rabbits, fish, and frogs, and found that it possesses a marked and prolonged stimulating effect. In addition a regulating or tonic effect on the heart was observed.

**Experimental Investigation on the Intravenous Treatment of Bacteremia with Bichloride of Mercury.**—E. B. Shklovskoy treated rabbits infected with a virulent streptococcus by intravenous injection of solutions of mercuric chloride. In doses corresponding to a nontoxic dose in man, no effect whatever on the temperature or the course of the infection was observed. In doses twice the maximum therapeutic dose for man, the temperature curve was somewhat changed for the better, but the final results were the same.

**The Wassermann Reaction in Pathological Anatomy.**—I. S. Galadze applied the Wassermann test to cadavers and found the reaction equally specific. In positive cases, the cerebrospinal, pericardial, pleuritic, and ascitic fluids gave just as satisfactory reactions as the blood. On the other hand, the blood of decomposed bodies could not be utilized for the test. The bodies of persons dead from tuberculosis, septic infections, and malignant growths, frequently give a positive Wassermann.

*June 1, 1913.*

**The Treatment of Pulmonary Tuberculosis by Artificial Pneumothorax.**—W. F. Oriolovskoy is of the opinion that the mode of action of artificial pneumothorax is far from being understood and requires further investigation.

**A Method of Counting Red Blood Cells.**—S. Ph. Krotkoff describes a simplified and, what he asserts to be a more accurate, method of counting red cells. It consists of a measuring bulb and a graduated pipette. The mixing of the measured quantity of blood with the diluent is accomplished in the mixing bottle. The mixing is thus much more thorough and accurate than in the usual pipette, and the blood count may be postponed for a day or more without the danger of unequal distribution of the cells. As a diluent he prefers Hayem's fluid.

**BRITISH MEDICAL JOURNAL.**

**August 9, 1913.**

The Treatment of Chronic Progressive Diseases of the Spinal Cord by X Rays.—F. Hermann Johnson reports two such cases which do not fit into any particular diagnostic group both of which improved greatly under the long continued use of small doses of x rays. It has been shown that the effect of small doses of the rays, or of radium, is to stimulate the growth of healthy adult cells, whereas the same doses may have a destructive or inhibitory action on proliferating and embryonal cells. The author suggests that the beneficial effect of the x rays in his cases may be explained on the basis of destruction of unhealthy neuroglial cells, together with stimulation of those neurons which were not too greatly injured to respond. Whether this explanation is correct or not, the mode of treatment seems to be the only one at present holding out any hope of relief.

**Veronal Rashes; with a Note on Luminal.**—Both of George Pernet's patients seemed to be abnormally susceptible to veronal for each responded to a small dose with the appearance of a diffuse, blotchy erythema in one, and a severe bullous eruption in the other. Each had taken the drug before and had had previous attacks of eruption. In one the eruption (bullous) came on within ten minutes after taking one small tablet. Her first sensation, about five minutes after swallowing the tablet, was of tingling in the mouth and a sensation of heat in the head. Her lesions were about the face, on the lips and hands, and were accompanied by general swelling of the head, orbits, and nose. In a third patient a morbilliform erythema developed as a result of taking three grains of luminal a day. Luminal and veronal differ only in the substituted alcohol radical. Pernet suggests that all three cases were anaphylactic to a portion of the common molecule.

**The Nature, Varieties, Causes, and Treatment of Lupus Erythematosus.**—J. M. H. MacLeod does not believe in the necessary relation of the disease to tuberculosis, and he points out that tubercle bacilli have never been demonstrated in the skin in lupus erythematosus. Opposed also to the contention that the toxins of tuberculosis may be the causative factors, he cites the fact that the disease has never been recorded as occurring from the use of the several tuberculins and tubercine vaccines. He holds that, apart from the probable causative factor being tubercle toxine, there is reason to believe that other toxins, at present unknown, may cause certain cases, especially of the acute, disseminated type. The tendency to the symmetrical distribution of the lesions; their similarity, often, to the toxic erythemas;
the histological similarity between the lupus lesions and those of the toxic erythemas; and the not infrequent association of lupus erythematosus with some of the more or less severe general toxemias, such as those of cirrhosis of the liver, renal diseases, alcoholism, etc., support the general toxic etiology. In all cases there are usually also some evidences of circulatory defects, such as cold hands and feet, moist palms, etc. Lupus erythematosus, therefore, seems to be "a persistent erythema, followed by atrophy and scarring, due to a variety of causes in a predisposed individual. The circumscribed cases have probably a different etiology from those of the acute disseminated type, and even different circumscribed cases, clinically closely resembling each other, may vary in their causation."

LANCET.
August 9, 1913.

The Value of Tuberculin in Pulmonary Tuberculosis.—James K. Fowler’s wide experience in the treatment of pulmonary tuberculosis in several sanatoria leads him to the conclusions that: 1. The use of tuberculin in any form in the treatment of the disease is not free from danger. Even with extremely small doses, gradually increased, the limit of tolerance may be reached suddenly and a reaction may occur. 2. In any case in which there is fever its use is absolutely inadmissible. 3. Fever is the guide to the activity of the disease, and, therefore, a remedial agent which can be used in febrile cases only is, of necessity, of very limited usefulness. 4. General reactions are to be avoided, and if one occurs treatment must cease at once. 5. Focal reactions are dangerous also, for they cannot be controlled. They may occur in the region of an obsolete lesion and lead to its reactivity with a resulting increase in the activity and severity of the disease. Such focal reactions have been known to cause the coughing up of calcareous masses and lung tissue with the development of a secondary cavity. 6. The most successful treatment should be on the lines of rest and exercise as originated by Walther.

Theses on Tuberculin Treatment.—Sahli holds opinions almost diametrically opposed to those of Fowler’s just recorded. He says that all the various tuberculins are identical, the apparent differences being due to admixed impurities. To prevent disastrous mistakes in therapeutic doses. Sahli advocates the providing of the practitioner with tuberculin in suitably graduated dilutions. He believes the use of tuberculin is unreliable both positively and negatively for diagnostic purposes. Treatment with tuberculin is free from danger only if the more obvious clinical reactions are avoided, in which case it is harmless. Tuberculin treatment is valuable chiefly in inipient cases. Its action is favorable only in cases not already sufficiently under the influence of absorbed tuberculin, generally, therefore, the slighter cases. There is an individual optimum dose which should not be exceeded, and it is not necessary to push the tuberculin to the greatest limit of tolerance. Tuberculin treatment is not a true immunisation, though it produces immunisatory effects in the organism. The production of a state of immunity is impossible in tuberculosis, and in tuberculin treatment all that is sought is a stimulation and activation of the counteractions of the body at each injection. All localized tuberculosis is suitable for tuberculin treatment if the patient’s system is not already overloaded with his own tuberculin. As a rule acute cases cannot be treated by tuberculin.

The Albumin Reaction in Sputum: Its Significance and Causation.—Percy B. Ridge and H. A. Treadgold conclude from examination of 2,164 cases that: 1. Practically all cases of active pulmonary tuberculosis contain albumin in the sputum. 2. Where tubercle bacilli are absent, a negative albumin examination on three successive occasions is strong evidence against active tuberculosis. 3. In doubtful early cases of pulmonary tuberculosis the presence of albumin lends support to the diagnosis. 4. In cases of chronic tuberculosis and emphysema a positive test is of considerable value as evidence of active disease. 5. There is definite evidence that the number of ordinary alveolar cells is greatly increased in sputa that contain albumin.

Basophile Patches in the Protoplasm of the Neutrophile Polymorphs.—A. Roemmele and R. Sweet saw many cells which contained from one to five of these patches in a case of acute infection with very high leucocyte count. The patches were irregular in form and took up the stain as well as the nuclei of the cells. Some were attached to the nucleus by fine basophile tendrils. As the disease retrogressed and the leucocytes decreased in number they became more typically normal and the patches were less frequently seen. They disappeared completely in about five days. The authors believe that these patches possibly indicate an early stage of the cell, for many immature polymorphs and marrow cells were present in the films at the same time that the patches were seen in the cells. Both Jenner and Glemsa stains were used.

CHINA MEDICAL JOURNAL.
July, 1913.

The Sanitary Organization of China.—Arthur Stanley says that from an administrative point of view the sanitary organization of China presents a fascinating problem. A collossal country with more than a quarter of the population of the world, quite devoid of all public effort to prevent disease, where evolution, operating through the survival of the fittest, has had full play; and, as a result, it is probably as eugenically sound as any country in the world. China may, however, justly be considered the fountain head of epidemic disease and, in the absence of modern hygienic methods, remains a danger to the world. The pandemics of plague, cholera, and influenza had their origin there. The comparative absence of rickets, gout, rheumatic fever, scarlet fever, and insanity is more than counterbalanced by the prevalence of smallpox, tuberculosis, the septic infections, plague, and cholera. There can be no doubt, the author thinks, that China is the finest field extant for the modern sanitary. There are many interesting problems connected with its sanitation. As to the present position of sanitation in China, it may be summed up somewhat as follows: The prolonged national life of the Chinese and their great population constitute an unanswerable argument to show that there is nothing radically wrong with their methods
of living. From the sanitary viewpoint many of these are sound, such as their dietary of sterilized food, disposal of waste for the benefit of agriculture, clothing, and comparative absence of alcoholism and prostitution. In a country like China, which is throwing off a civilization in which science formed no part at all, it appears desirable that sanitation should be organized from above downward. The first essential is considered to be the establishment of a central health office, whose business it would be to study comparative sanitation as applied in various other countries and in the places in China where modern sanitation has been put into practice under foreign control. An essential part of this central office would be a laboratory for the practical study of disease prevention. Little progress can be made without the organization of an adequate system of vital statistics, and without skilled medical attendance the requirements of sanitation cannot be met. The organization of medical practice by the government will come sooner or later. The head of the government medical service would have to be a statesman of the highest rank, as statesmanship of the finest type would be required to organize such a service to deal with disease in all its aspects among all classes, with compulsory powers scarcely dreamed of at present.

Results in Thirteen Cases of Dysentery Treated with Emetine.—A. C. Hutcheson reports the following conclusions from these cases: 1. Emetine in amebic dysentery is simply wonderful in its efficacy. 2. In undiagnosed cases of chronic dysentery it will succeed in the majority, as most of these are amebic. 3. In double infection of ameba and schistosomum it will kill the ameba and probably stop the dysentery. 4. In pure schistosomum cases it is at least worth trying. In seven of the thirteen cases the ameba was found on examination. One case was apparently amebic, though examination of the stools failed to show the presence of amebae. The patient left the hospital on the seventh day cured of symptoms. In two cases there was infection with both the ameba and Schistosomum japonicum. In three cases the infection was with schistosomum alone. All three were chronic cases. In two, blood had disappeared from the stools on the sixth day, under emetine. In the third case the patient left after seven days, showing no improvement. In this case the author found an active miracidium at the end of the treatment, which he thinks would rather argue against the efficacy of emetine, at least as far as affecting the eggs is concerned. The emetine in these dysentery cases was administered in one third grain doses of the hydrochloride, twice daily, by hypodermic injection.

INDIAN MEDICAL GAZETTE.
July, 1913.

Note upon Some Unusual Forms of the Parasite of Pernicious Malaria, Found at an Endemic Blackwater Fever Centre, in Blood Smears from Certain Children.—N. P. O'Gorman Lalor describes his findings with illustrations that vivify the text. They are freehand drawings of the originals as seen under a Leitz 1/12, an oil immersion objective, and a No. 4 eyepiece (Leishman's stain). The earliest form consists of a spore surrounded by a thin, darkly staining blue envelope. The cytoplasm of the spore is stained blue, stippled with spots of a darker color, and the spore contains at first a single chromatoid mass laterally situated, which is replaced later by three or four chromatoid rods, surrounded by an ameboid area. These spores have been observed, their envelopes having been ruptured and discarded, to become incorporated with the nuclei of certain large mononuclear cells, apparently of endothelial origin. In a single instance one of the spores was found in a red cell. After this incorporation the spores grow within the nucleus and becomes covered with accretions of nuclear material which appear to be derived from the nuclei of broken down white cells. These accretions cause the nucleus of the cell host to stain a very deep and opaque purple color, which obscures all but the earliest and latest development of the intranuclear parasite. Eventually six large spores are seen to separate from the nucleus, each covered by an envelope derived from the nucleus accretion, and each is seen to have divided into two within its envelope. In such a cell the large, faintly staining red nucleus affords an excellent background to the deep purple rosette stage of the dividing parasite, the central area of which is seen to consist of an amorphous mass of smoky appearance surrounded by the six double spores into which the parasite has divided. These deeply staining spores become free in the blood through the rupture of their nuclear sac and eventually appear either as typical malignant plasmodia in the red cells of the blood, or as malarial crescents of typical appearances, except as regards the cytoplasm of the male crescent, which takes on a pinkish coloration, and the deeply staining purple envelope of definite organic nature which surrounds crescents of both types and seems to be the remnant of the envelope of the original spore from which each was derived. The parasite itself in its early stages in the red cell appears intensely malignant. The containing cell is small and shrunken, and either heavily marked with Maurer's clefts, or stippled over with pale pink patches of circular or irregular shape. The cytoplasm of the parasite is coarser, stains a deeper blue, and is much more pigmented than is usual with the ordinary parasite of malignant fever. Both have been found associated in some specimens and comparison between them seems to render it certain that though they may have a common origin as well as a common association, they constitute not one, but two different and distinct types of malarial plasmodium.

BOSTON MEDICAL AND SURGICAL JOURNAL.
August 14, 1913.

Diagnosis of Typhoid Fever on Admission to a Hospital.—George Cheever Shattuck and Charles Henry Lawrence have tabulated the facts from the records of a series of 231 cases, in the Massachusetts General Hospital, in which the diagnosis of possible typhoid was made, and for which precautions were ordered at the time of entrance. Their conclusions are as follows: 1. When patients suffering from febrile conditions which have lasted from a few days to a few weeks enter a hospital for
treatment, typhoid fever should be suspected until some other diagnosis seems reasonably certain. Meanwhile, these patients should be treated under precautions to prevent the possible spread of infection. If this is done it is possible to avoid risk of spreading infection in nearly all instances. 2. In a series of 100 nontyphoid patients of fourteen years of age or older, in which typhoid fever was suspected, bronchitis, bronchiectasis, and influenza represent twenty-nine per cent., or nearly one third of the whole, undiagnosed fevers fifteen per cent, and gastroenteritis, diarrhea, and colitis twelve per cent. 3. The importance of these diseases in the differential diagnosis from typhoid has not been sufficiently appreciated. 4. Absence of rose spots at the first examination has little weight for diagnosis. The same is true of splenic enlargement when not demonstrable by palpation, and of the Widal test when negative. 5. A positive Widal test is of the greatest importance. Typical rose spots are very important, and a palpable spleen is a valuable indication of typhoid, but is common in various conditions simulating typhoid. 6. Atypical rose spots are useless for diagnosis. 7. Absence of leukocytosis in a febrile disease strongly suggests typhoid. A white count below 5,000 is a valuable indication of typhoid fever, and is unusual in conditions simulating typhoid. 8. A white count above 9,000 is presumptive evidence against typhoid. 9. Bronchitis has no weight per se for or against the diagnosis of typhoid fever. Patients with ordinary bronchitis entered the hospital during the first week, and with typhoid with signs of bronchitis generally during the second week of illness. 10. Congestion of the bases of the lungs, when present in febrile disease uncomplicated by cardiac insufficiency, points to typhoid. 11. The temperature in typhoid fever seldom is below 101° F., whereas, in other conditions simulating typhoid, the temperature is commonly below 101° F. 12. In typhoid the pulse rate is more apt to be low in proportion to the temperature than in other diseases.

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.

August 16, 1913.

The Local Specific Therapy of Infections. 1. The Biological Basis.—Simon Flexner, in the first of two lectures, presents the main facts which have to be taken into account in the working out of a system of specific therapy of the infectious diseases, and states that from these it must be evident that the solution of this problem is bound up in no small way with the problem of the segregation of the parasitic causes of infection in relatively inaccessible portions of the body. Hence, the recommendation which he brings forward is that of a more direct mode of attack on the local processes of infection that are not readily, if at all, to be reached by the introduction of curative agents into the blood. It is patent, he says, that a method enabling the healing substances to be delivered in and about the seat of disease and made to exercise their effects on the parasites, not through a diluted lymph secretion, but in such a state of concentration and combination as experiment and experience prove in given instances to be useful, offers high hopes of success. So far as the surfaces of the body are concerned the method of local treatment, generally considered, is time honored; but even with the injections of these surfaces it has been too little practised.

Overresponse to Affective Stimuli from Stationary Cortical Lesions.—G. W. Robinson reports this case, that of a house painter who came under observation in February, 1913, complaining of partial paralysis of the right side, morphine habit, and occasional epileptic seizures. Eight years previously he had received a fracture of the skull from a fall from a scaffold and was operated upon immediately. Soon afterward he suffered from a cerebral abscess, which was drained, and a considerable quantity of brain tissue removed with the curette. After this he had convulsions at frequent intervals. In 1911, in an attempt to cure the convulsions, another operation was done, and a considerable amount of skull and brain tissue removed. The author states that the lesion was so extensive and penetrated so deeply into the cortical structures as to interrupt the corticothalamic fibres and interfere with cortical inhibition of thalamic activity. In interpreting the symptoms met with in this case he suggests that perhaps the rather frequent attacks of Jacksonian epilepsy and occasional general epileptic attacks produced the unstable nervous state to which Monakoff applied the term diachesis, and that this state was responsible for the overresponse to the various forms of measured stimuli employed. During many examinations he found no variability or instability of response.

Cloudy Swelling, by E. T. Bell.—See this JOURNAL for June 28, p. 1371.

Experimental Cirrhosis of the Liver, by A. L. Grover.—See this JOURNAL for June 28, p. 1371.

Attempts to Transmit Poliomyelitis by Means of the Stable Fly.—The following conclusions were reached by W. A. Sawyer and W. B. Herms: 1. In a series of seven experiments, in which the conditions were varied, they were unable to transmit poliomyelitis from monkey to monkey. 2. Further experimentation may reveal conditions under which the stable fly can readily transfer the disease, but the negative results of their work, and of the second set of experiments of Anderson and Frost, lead them to doubt that the fly is the usual agent in spreading this disease in nature. 3. On the basis of the evidence now at hand we should continue to isolate persons ill with poliomyelitis, or convalescent, and we should attempt to limit the formation of human carriers and to detect and control them. Screening of sickrooms against the stable fly and other insects is a precaution which should be added to those directed against contact infection, but not substituted for them. 4. The measures used in suppressing the house fly are not applicable to the control of the stable fly, owing to its different breeding habits and food supply.

Rest and Repair in Pulmonary Tuberculosis.—J. W. Flinn believes that although much good work has been done in the last ten years in the way of serums, vaccines, and other special treatments, so
much has been written along these lines that we are apt to forget that fresh air, good food, and rest are still the *sine qua non* of treatment in this disease. The truly wonderful effects of fresh air and good food have long been known to the profession, but rest, he says, is an agent the use of which the profession has been slow to recognize. As all three are of such importance, it is difficult to compare them, but perhaps one cannot better express their relative importance than by a paraphrase. "In the treatment of pulmonary tuberculosis there now abideth fresh air, good food, rest, these three; but the greatest of these is rest."

**Epididymotomy; the Radical Operative Treatment of Epididymitis.**—L. S. Eckels expresses the opinion that epididymotomy should be the treatment of choice in all cases of epididymitis, due to whatever cause, and for the following reasons: Relief from pain is instantaneous; internal administration of sedatives and opiates and loathsome external applications are unnecessary; the abatement of fever takes place in from twenty-four to forty-eight hours; pus and abscess formation are prevented; swelling, tenderness, and other symptoms rapidly disappear; there is no tendency to relapse; it insures a minimum of time lost from usual activities; there is probably a smaller proportion of sterility following the disease.

**Symptomatology of Multiple Sclerosis,** by L. H. Mettler.—See this JOURNAL for July 5, p. 47.

**Some Nervous Symptoms of Pernicious Anemia,** by C. E. Riggs.—See this JOURNAL for July 5, p. 47.

**MEDICAL RECORD.**

*August 16, 1913.*

**The Wassermann Reaction in Cancer.**—F. J. Fox reports a series of 215 cases, which are presented in two tables. Table No. 1 is made up of 210 cases, all of which gave negative results. Forty-nine were epithelioma; seventeen, sarcoma; 141, carcinoma; one, cerebral glioma; one, malignant papilloma of tongue; and one, papilloma of chest. In table No. 2 are placed five cases (four of carcinoma and one of sarcoma) which gave positive reactions. The technic employed is described, and it is stated that with each series tested the following controls were made use of: 1. Antigen control; 2. Serum control; 3. Hemolytic system; 4. Known specific serum, with and without antigen; 5. Known negative serum. The series was further controlled, in a measure, by 1,300 reactions done in the same series as those on cancer cases. The author regards it as fair to conclude, from the results in his cases, that cancer rarely, if ever, gives a positive Wassermann reaction under a technic like that employed, and that, in the presence of a positive finding, a coexisting luetic infection should be suspected.

**Specifics in the Treatment of Tuberculosis.**—G. R. Pogue states that "our first aid to Nature," the use of tubercle vaccine, can be effective only when the lesions are open and tubercle bacilli are free in the tissues, and then only when the total sum of the open and closed lesions is not great enough to overwhelm the tissues with toxic products, or when other factors which might lower the reactive powers of the tissues are absent. In speaking of the use of tuberculin, "our second aid to Nature," he says that if the dose is kept down to such an amount as to cause only a slight focal reaction, and all of each dose neutralized or taken up by the antibodies in the tuberculous tissue, there will be no excess of tuberculin or antigen left free to stimulate extra antibodies. In so called closed tuberculosis it is this local reaction which we wish to produce, so that we may get more blood supply to the focus. Tuberculin does its work only when properly administered and when proper conditions are present. Later, the author takes up the pyogenic bacteria occurring in tuberculous lesions. Laboratory and animal experiments do not give much information regarding the part played by these in tuberculous lesions, but clinical experience and specific therapy directed against such mixed infections have proved that associated bacteria do play a large part in producing the symptom complex of the disease. Against these, autogenous, and not stock, vaccines should be used; for any antibodies which may be produced in the tissues are specific for the offending organism. It should be understood that the specific treatment of tuberculosis and its associated infections is not advocated to the exclusion of other known and tried therapeutic measures. All other measures known to have a favorable influence on the disease must be employed to suit the individual case.

**Pathology and Treatment of Appendicitis.**—B. S. Purse says that of the conditions causing appendicitis, the overloaded colon and cecum are the exciting factors. The opening from the cecum is usually patent and free, though at times a fold of mucous membrane presents a more or less rudimentary valvular formation here. The open or normal condition is the safeguard of the appendix, because its contractile fibres are thus enabled to reject any offending matter which has been crowded into it. In an appendix with the valvular formation, appendicitis cannot occur unless this resisting power of the appendix has been overcome by repeated attacks of constipation. In that case dilatation of its lumen takes place, and we have abortive attacks which can be readily relieved by purgatives. Where simple and conservative medical treatment is neglected the retained organic contents of the dilated appendix, decompose, cause inflammation of the mucous lining and adhesion of the outlet, and give us a typical abscess cavity. The folds of the peritoneum act as a defence against the entrance of any intestinal matter through a ruptured appendicular abscess into the general peritoneal cavity. The contiguity of the inflamed surfaces of the appendix with these peritoneal surfaces produces an adhesion which retards the escape of the appendicular contents, and by the rapid secretion of lymph a new cavity, with thick walls, is formed which, through its connection with the intestinal canal, becomes temporarily a part of that canal, taking the place of the appendix. As
to the treatment, it is first necessary to eliminate the cause, namely, the accumulated and hardened contents of the cecum and colon which block up the appendicular opening, and thus facilitate the reflux of the appendix's contents back into its natural channel. The treatment recommended, the author states, is simple, and usually successful in all stages of the disease: Empty the intestinal tract by purgatives; feed the patient with such food as will leave the least residue; and make constant application of hot poultices backed up with hot water bags.

The Etiology of Blackwater Fever.—George Richter proposes the following theory, based, he says, on many well known facts, to explain the symptoms of this disease. Material derived from the decomposition of "aged" erythrocytes is converted in the liver into bile pigments. These are changed by bacterial action in the intestine into urobilin, which is in part reabsorbed and through the portal circulation enters the liver, to be again transformed into bile pigments. The source of bile pigments is therefore hemoglobin derived from the circulating blood and urobilin derived from the portal circulation. When either source supplies an excess of material, urobilin will pass through the capillaries of the liver unchanged, enter the general circulation, and be excreted by the kidneys; the result is urobilinuria. In malaria erythrocytes are destroyed by the plasmodia, and as long as plasmodia are present we always find a urobilinuria. A coincidence of insufficiency of the liver (perhaps heretofore occult and also due to malaria infection), of malarial blood, and, eventually, of the toxic effect of quinine upon enzymes (bile forming), will have the effect that not only portal urobilin is not converted into pigments, but that the free hemoglobin in the plasma (derived from destroyed red cells) is not transformed in the liver, but arrives in the kidneys, giving rise to hemoglobinuria (blackwater fever).

The Production of a Safe Municipal Milk Supply.—G. G. Nasmith, who is director of the laboratories of the Department of Health of Toronto, Canada, states that the following are the observations demanded by the Toronto health department, as essential for the safety and purity of the milk supply: 1. Washing and sterilization of all bottles and cans after use in city delivery, and of all cans before being returned to producers. 2. Sealing all empty returned cans. 3. Milking from cows with washed udders, in clean stables. 4. Milking into clean, preferably small-mouthed, sterilized pails, by clean milkers. 5. Immediate chilling of milk, and keeping it below 50° F., in clean milk houses, until collected. 6. Rapid delivery of the milk to the city in sealed cans, with some mark of identification on the seal. 7. Holding the milk below 50° F. at the dairies in the city until pasteurized and bottled. 8. Using of utensils and machinery thoroughly washed with water and sterilized by steam. 9. Pasteurizing all milk to destroy pathogenic organisms, which, in spite of all precautions, will gain entrance to the milk. 10. Allowing only bottled milk to be sold, and thereby obviating all possibility of contamination subsequent to pasteurization.

Tuberculosis of Bones and Joints.—C. L. Starr says that, in his experience, glandular enlargement of the mesenteric glands, with or without tuberculous peritonitis, in children, is not common, as compared with infection of the cervical, bronchial, and mediastinal glands. Also, a careful study of the morphological character of the bacilli from a large number of abscesses and broken down tissues reveals very few of the bovine type. Thus his experience would suggest that the bulk of the infections take place through the respiratory tract (the tonsils being responsible for a fair proportion of these), and that the infections from tuberculous milk or meat are uncommon. In the treatment the author emphasizes the point that the main feature should be the endeavor to increase the resistance of the patient, who should be given the advantages of fresh air, sunshine, the best hygienic surroundings, and good food, as in the treatment of tuberculosis elsewhere. The mechanical support of the affected part should, as a rule, be so applied as to limit the movement of the part and, at the same time, allow the child the advantage of exercise. An acute abscess should never be opened if it can be avoided.

The Use of Tuberculin.—E. S. Harding sums up an article on the use of tuberculin in pulmonary tuberculosis by saying that sanatoriums are essential for training the febrile patients, and for the leisure class with means. The universal treatment of patients, however, must be done at the dispensary, and the most efficient dispensary treatment is with the aid of tuberculin. At the Royal Edward Institute in Montreal he has been largely using bouillon filtré (BF), but for the past five months has employed Perkucht tuberculín original (PTO) almost exclusively on new patients, and found it less liable to intense reactions. In regard to reactions, he is rather particular in using B F to avoid anything in the nature of a reaction, but in using PTO generally disregards slight reactions.

The Diagnosis and Treatment of Eclampsia.—The following is a summary of a paper on this subject by G. W. Kosmak: 1. The diagnosis of the toxemias of pregnancy should be made with certainty in every case, especially in the presence of convulsions. 2. Treatment should be governed by the signs and symptoms presented by the individual patient; thus far no specific therapeutic measure has been found. 3. When labor is imminent especially at term, it may be completed by rupture of the membranes, manual dilatation of the cervix, version, or forceps, unless some indication is present for a more radical operative delivery. If the patient is not in labor, or pregnancy is not more advanced than the seventh or eighth month, conservative, mainly sedative and eliminatory measures should always be instituted before resorting to any radical operative procedures. 4. The presence of a single convulsion should never be accepted as the criterion for radical surgical interference.
ARCHIVES OF OPHTHALMOLOGY.

July, 1912.

Parinaud's Conjunctivitis; a Myotic Disease Due to a Hitherto Undescribed Filamentous Organism.—F. H. Verhoeff states that he has discovered masses of a filamentous microorganism in the focal areas of cell necrosis characteristic of Parinaud's conjunctivitis in eleven out of twelve cases. He fixes the tissue with Zenker's fluid, places it when hardened in absolute alcohol over night; he then places it on a cover slip kept wet with absolute alcohol, and scrapes its cut surface with a knife. The scrapings are allowed to dry on the cover slip and may then be stained, or sections may, however, be made of the tissue and then stained. When hematoxylin and eosin, the ordinary Gram stain, or the tubercle bacillus method is used, the microorganism is invisible. Carbolthioin gives fairly satisfactory results, but inferior to those obtained by the modified Gram method. Wright's modification of Leishmann's stain enables the microorganism to be recognized. The best results are obtained by a modified Gram stain, in which the essential difference from the ordinary Gram lies in the preliminary treatment of the sections with xylol balsam. Paraffin sections are preferable. They are first immersed in xylol balsam in the usual way and left for five minutes or longer, then treated rapidly in succession with xylol, chloroform, 95 per cent. alcohol and water, and then stained as follows: Aniline gentian violet, five minutes; water, Lugol's solution, thirty seconds; water; 95 per cent. alcohol until excess of color is removed—about one minute; chloroform to differentiate and dehydrate—about ten seconds; wash thoroughly in xylol; xylol balsam. Remove balsam as before and repeat staining process. The microorganisms occur in irregular masses from ten to sixty micra in diameter, but isolated individuals are also seen. The masses are composed of extremely delicate filaments intertwined together. The individual filament is extremely delicate, stains faintly, and has a single contour. It may be apparently straight, but is more often irregularly curved. Intensely stained round dots occur along the filament at almost regular intervals, never exactly centred in the axis of the filament, but projecting above its surface. As no branching could be made out he thinks they belong to the class of leptothrix. The absence of any other demonstrable microorganisms in the lesions, the unusual character of the microorganisms found, their great abundance, and the fact that they were so situated as to explain the lesions, leave no doubt in the mind of the writer that he has discovered the hitherto unknown agent of this disease.

Toxic Amblyopia Due to Tobacco Alone.—Matthew L. Foster reports a case in which toxic amblyopia developed in a man, sixty-five years of age, who had been an inveterate smoker for many years, but had maintained the reputation of a total abstainer from alcoholic liquors for over forty years in a community in which he was well known, and had no symptoms of multiple sclerosis, or of any other disease of the central nervous system. The difficulty of proving that any man does not drink is admitted, but the writer thinks the reputation borne by this man for so long a time is the best negative evidence possible that he could not have indulged in alcoholic beverages in sufficient quantity, and with sufficient regularity, to excite a toxic amblyopia. An almost perfect recovery followed total abstinence from tobacco and treatment with strychnine for a period of eleven months. Almost all cases of this disease have been due to the combined action of tobacco and alcohol, but this one case the writer thinks enough to prove that it may be caused by tobacco alone.

Proceedings of Societies.

MEETING OF THE NEW YORK NEUROLOGICAL SOCIETY.

Held at the N. Y. Academy of Medicine, June 3, 1913.

The President, Dr. Smith Ely Jelliffe in the chair.

Brain of Patient with Cortical Astereognosis.—Dr. Louis Casamajor and Dr. Smith Ely Jelliffe. The patient from whom this specimen was obtained was a woman, forty-three years old, a housewife, born in this country. On June 3, 1912, she was suffering from paralysis of the right side of the body and inability to recognize objects in the right hand. Her father died, at the age of fifty-one, of asthma; her mother, at the age of fifty-nine, of apoplexy. There was no history of neuroses nor psychoses in the family. The patient had been married for twenty-four years, and was the mother of two children, one living and one dead. She also had two miscarriages. The history obtained from the patient was that she had enjoyed good health until July, 1910, when she began to suffer from severe headaches, which were almost continuous. After improvement under treatment, the headaches returned in May, 1911, and were continuous and severe. About two months after this the right arm began to feel weak, and later the corresponding leg was similarly affected. At that time she consulted Doctor Jelliffe, and he made a diagnosis of brain tumor in the left supramarginal gyrus. The weakness and stiffness in the arm and leg continued, and in November, 1911, both of these extremities became paralyzed, so that the patient could not get out of bed and was unable to hold objects in her right hand. At this time an operation was advised, but refused. The patient was given a course of mercury and iodide. Examination showed a spastic hemiplegia, with marked astereognosis in the right hand, and sensory aphasia with paraphasic speech. The fundi were normal. Under mercurial treatment, the patient improved considerably: the headaches disappeared, the weakness was less pronounced, and she was able to walk about the house and go on the street. Her skin had a distinctly bronze color, which came on rather rapidly about two years ago, but which she thought had not progressed much of late. On account of the bronzing of the skin, together with the x ray findings, an exploration of the kidney region was made; the supra-
renal body was found to be normal, while the kidney itself was the seat of a chronic nephritis. The patient returned to the hospital on August 9, 1912, with the statement that she had been entirely well until the previous day, when she was taken with a severe headache, with involuntary twiddlings and spasms of the right side of the body, but most pronounced in the right leg. At this time she also developed an internal strabismus. An examination of the eyes, made on August 29th, showed that the pupils were small and reacted normally. The ocular movements were slow, but complete. There was no nystagmus; no facial paralysis; sensation was normal. The right upper extremity was more spastic than at the time of her former stay at the hospital. The astereognosis in the right hand was unchanged. During the summer of 1912 the patient grew progressively weaker; she seemed confused and at times almost comatose. The ocular movements varied from day to day; sometimes there was double internal strabismus; at other times only weakness of the external rectus. Death occurred in November, 1912. The patient's brain had not yet been examined, and the report thus far was to be regarded as only preliminary. The pathological findings were a depressed area of softening just above the supramarginal gyrus on the left side, and a general atrophy of the convolutions of the left hemisphere.

Cortical Astereognosis from a Cyst: Operation, with Improvement.—Dr. J. Arthur Booth presented a young man of twenty-two, who was a perfectly healthy and intelligent lad until July 12, 1906, when he met with the following accident: He was on a spindriver and attempted to descend to the dock by sliding down a rope. When about thirty-five feet from the ground one of his companions jerked the rope and he fell, striking on his head and right arm. He was taken to the hospital, where an examination revealed a compound, comminuted fracture of the right parietooccipital region and of the right forearm. He was unconscious for five days, but finally made a good recovery, and, after a period of seventeen days, was discharged as cured. After his return home it was noticed that he was dull and stupid and quite changed from his former self. A year later he had what was called one or two "sinking spells," without any spasmodic movements of the muscles. He had one attack in 1908, another in 1909, a third in 1910, a fourth in 1911, and two in October, 1912. In March, 1913, he had three attacks, and during the following month he had two, which he described as follows: "I feel a tingling and numbness in the right hand: it is then drawn up and I feel my head turning to the right: then I lose myself." His mother stated that he then became stiff all over, and that on one occasion he had bitten his tongue. Besides these epileptoid attacks he frequently had severe headaches, limited to the left frontoparietal region, the pain being so severe at times that he had been noticed to pound his head with his fist. Examination by Doctor Booth, April 15, 1913: From a bright, intelligent schoolboy, standing at the head of his class, he was now apathetic and dull; all mental processes were slow, with a very faulty memory both for recent and past events. He answered questions slowly and hesitatingly, but there were no motor speech defects. The superficial and deep reflexes were present and normal, excepting the knee jerks, which were exaggerated; there was no ankle clonus nor Babinski. The tongue was protruded in a straight line, and there was no paralysis of the facial muscles. The equilibrium was fairly good. There was no marked ataxia. He was right handed, and the right upper extremity was weaker than the left, though it must be remembered that the right forearm was broken at the time of the accident. There was a decided loss of sensation over the right upper extremity, and to a lesser degree on the right side of the face, as compared with the left. The same applied to the right thigh, as compared with the left. The patient was unable to write anything but his name, which he did slowly and with difficulty. He could, however, write from copy. There was no transposition nor misuse of words. He was able to count up to 100, and recognized figures when they were placed before him. He was unable to recognize but two letters of the alphabet, namely, A and P, and he could not read the simplest word nor sentence. When blindfolded, he failed to recognize a bottle, knife, watch, coins of different denomination, chain, key, or pipe with the right hand, but readily did so with the left. The pupils were widely dilated, but reacted slowly to light and accommodation. The fundi were normal. Taking into consideration all these findings, a diagnosis was made of a cyst in the left angular gyrus, the result of a former hemorrhage. An operation for its removal was advised. The cyst found upon operation was about the size of a silver half dollar, situated over the left angular gyrus, extending forward and bound down with adhesions. These were freed and a drain placed in the cyst cavity after it was completely emptied of about two drachms of clear fluid. On June 3rd, when Doctor Booth saw him again, the patient had gained ten pounds in weight. Mentally, he was much brighter and there was a marked improvement in his memory. He had had no further convulsive attacks and no headache. There was still slight weakness of the right hand, with marked astereognosis. He could recognize a majority of the letters of the alphabet, and could read a few simple words and two short sentences.

Dr. William M. Leszyński said that in connection with these two cases with astereognosis he wished to report briefly a case that was recently under his observation. An examination of the patient revealed complete astereognosis in the left hand, and, in addition, a typical Babinski plantar response on the same side. There were practically no other symptoms. No rigidity; nothing in the eye grounds. Within a week, rigidity began to develop in the left lower-extremity, followed by partial paralysis. Subsequently, these symptoms extended to the left upper extremity, and about a week later the first eye symptoms appeared in the shape of a slight papilloedema. A subcortical lesion originating in the upper gyrus of the parietal lobe was diagnosed. An operation was advised. Before it could be undertaken, however, the boy became comatose and died. An autopsy was re-
fused. In this case, the lesion apparently developed in the parietal lobe and extended to the leg and arm centres.

Dr. I. Abrahamson said that in the case reported by Doctor Casamajor and Doctor Jelliffe, the condition simulated a tumor. The speaker said he had seen four cases during the past year, where choked disk and the other symptoms that were present were strongly indicative of a tumor of the brain, but eventually they all proved to be cases of nephritis, and no tumor was found.

Doctor Jelliffe, speaking of the patient with cortical astereognosis reported by Doctor Casamajor and himself, said that for a long time they were in doubt whether or not they had to deal with a brain tumor, but in view of the very gradual extension of the process, it was decided that if there was a new growth in the brain, it was of such a nature that its removal would be practically impossible—that if it was a new growth, it was probably of an infiltrating nature. The result showed that it was an infiltrating process in the nature of a diffuse atrophy, with specially intense development in one area; the true nature of the atrophic process had not yet been determined.

A Case of Myotonia Atrophica.—Dr. Foster Kennedy said the rarity of this curious muscular degeneration was his excuse for the report of a single case. The patient was a male, single, forty-six years old, a native of Switzerland, who was admitted on March 17, 1913, to hospital. The patient’s parents had both died in old age. He had three brothers and three sisters in good health. One sister, a resident in the United States, had arthritis deformans. There was no neuropathic family history: neither the patient nor his sister knew of any near or collateral relative affected in any way similarly to the case under consideration. For fourteen years the patient had been employed as a farmer in New England. His habits were regular and his general health good. His consumption of alcohol was limited to two or three glasses of beer a day. He denied venereal disease. His previous health had always been good. In 1893 his left cornea was injured by a burning spark falling on it from a passing engine. In 1887 his hands and feet were said to have been frostbitten. In November, 1911, after hard work in harvest time, he began to suffer from cramp-like pain in the lumbar region. These pains were at first intermittent and rare, but later became more frequent, so that at the time of examination he complained constantly of their presence. He could recall no injury to account for these pains, which were more severe when he worked in a bent posture. He strenuously denied having had any difficulties in his gait or in the use of his hands, and gave no history of sphincteric trouble. He had not worked for a year, but was never confined to bed. His facial appearance was quite strikingly characteristic, and was the result of an incomplete ptosis of both eyelids, with marked hollowing of the temporal fossae, and flattening of the masseter region on each side. The orbicular muscles of the eyes were very weak, and there was no movement in the temporal or masseter muscles. The left pupil was hidden by a corneal scar, the result of the injury just related. The reaction of the right pupil was normal. A well marked and advanced cataract was present on each side; that on the left side might have been thought traumatic in origin had not that in the right lens been so obviously otherwise. A slight, bilateral divergent strabismus was evidently a result of defective vision. The patient’s articulation of both English and French was slurred and difficult to follow: no structural defect was found which could account for this symptom. The sternomastoid muscles were completely atrophic, and there was some wasting in the extensor muscles of the forearms. The position of rest of both hands was one of slight flexion, the thumbs being strongly adducted. All movements were present, but it was found that after making a strong grasping movement with either hand, he was unable quickly to again extend the fingers, the involved muscles, apparently, being in a state of cramp. If the grasping movement was frequently and quickly repeated, this cramp became less and less noticeable, until after perhaps a dozen efforts it would completely disappear. This phenomenon was not present in any other muscle or group of muscles. The abdominal muscles and those of the back and chest were normal, as was also the spine. The vastus internus and externus of the right thigh were diminished in bulk, though no change was found in the intervening rectus femoris muscle. The knee jerk on the right side was difficult to obtain—a reduction in response directly proportional to the reduction of the muscular mechanism involved. There was almost complete atrophy of the anterior tibial and peroneal muscles, with complete bilateral foot drop as a result. The ankle jerks and plantar reflexes were absent. The abdominal and arm reflexes were normal. The gait was of the steppage character peculiar to paralysis of the dorsiflexors of the feet. There were no sensory changes. No reaction to faradism or galvanism in the orbicular eye muscles, the temporalis, masseters, or sternomastoids, and almost complete loss in the anterior tibial groups of both sides. In the muscles of the forearms and in the intrinsic hand muscles, the reactions were strong, but enormously prolonged. There were no pathological changes in either the blood or urine. The Wassermann test of the blood serum and of the cerebrospinal fluid was negative. The combination of premature bilateral cataract with atrophy of the temporal and orbicular eye muscles, and of the masseters, sternomastoids, vasti, and anterior tibial muscles, together with a sharply contrasted myotonia in the hands occurred too infrequently to be ignored, and most probably pointed to a deficient hereditary endowment as the approximate cause of the disease.

Dr. I. Abrahamson referred to a typical case of myotonia atrophica: The patient had bilateral cataract and there was a congenital absence of certain muscles, such as the sternal portion of the pectorals. In another case, now under observation, the symptoms were strongly suggestive of myotonia atrophica, the patient presenting a fibrillary twitching of the tongue, etc., with weakness of one sternomastoid; yet, owing to the fibrillary twitching, etc., it was most likely not a case of myotonia.
Doctor Kennedy said a peculiar feature of myotonia atrophica was the extraordinary uniformity in the appearance of these patients. They all looked as though they belonged to the same family—like brothers and sisters. There was more uniformity in their symptoms than in other forms of dystrophy. The electrical reactions showed a quantitative change in the atrophied muscles, but in the forearm there was increase in the reaction to both galvanism and faradism, and the reactions were very long drawn out. The muscles easily went into a tetanoid condition, which was at complete variance with the action of the atrophied muscles.

Cauda Equina Neuritis.—Doctor Kennedy presented an Italian, forty-nine years old, who was admitted to his care on May 8, 1913, with the history that five years ago he developed a severe pain in the middle of the back, subsequently extending to the left leg and later to the right. It was shooting in character, and after persisting for several months it was said to have disappeared after the injection of morphine. Later, he noticed a “dead” feeling in both legs: this progressed, and walking became more and more difficult until he was bedridden. There was no history of incontinence, but he stated that since the onset of his illness he had to strain before passing urine. He was bedridden for two years, when he began to regain power in the legs, and the improvement slowly continued until he was able to walk. He now walked fairly well, but was handicapped by double dropfoot. The upper extremities had never been involved. There was now no pain, but occasional pin and needle sensations in the feet. Examination showed marked atrophy of the tibialis anticus and peronei muscles, and the symptom complex was referable to a lesion of the cauda equina, which at one time we might have attributed to the presence of a tumor in that region, but in the cases which the author had reported at the recent meeting of the American Neurological Association in Washington they had found no tumor, but a congested appearance of the nerve roots. In this case the patient, after being bedridden for two years, had gradually improved, which we would not expect to find with tumor, and we were therefore justified in believing that these cases were due to a lesion which was not lytic, nor to the presence of a new growth, but rather to an infective, inflammatory state of the cauda equina, possibly a neuritis.

Doctor Leszynsky said that in certain cases of this type, in which the patients presented symptoms of tumor of the cauda equina, puncture of the spinal canal had failed to give any fluid, and this might serve as a differential point between neuritis and neoplasm.

A Case of Multiple Sclerosis Treated for Incontinence.—Dr. I. Strauss reported this case. The patient was a man, forty-seven years old, who was admitted to the hospital on December 5, 1912. His family history was unimportant. The patient was a moderate user of alcoholics and gave a history of gonorrhea and syphilis twenty years ago. Two years ago it was noticed that the patient had difficulty in remembering things, with slowness of speech and motor aphasia. Eight months ago he complained of weakness in the legs when walking, and two months later he developed vesical incontinence, with occasional rectal incontinence. There was also diplopia and loss of weight. An examination at the time of his admission to the hospital showed, in addition to the above symptoms, nystagmus, tremor of the head, exaggerated knee jerks, slight Romberg, slow speech, and diminished abdominal reflexes. A cystoscopic examination showed a trabeculated bladder, with a mild cystitis. The Wassermann test at this time was negative. Under repeated injections of salvarsan and epidural injections of sterile petrolatum, the patient gradually regained control of his bladder function, and he left the hospital, on May 1, 1913. He was urinating about five times in the course of twenty-four hours, and was able to retain urine from six o’clock p.m. to six a.m. without discomfort.

Hysteroepilepsy (Piblokto) among the Eskimos.—Dr. A. Brill presented a paper on this subject, in which he said that while reading Peary’s fascinating book, “The North Pole,” he was especially interested in what Peary called a peculiar form of nervous affection found among the Eskimos of the Western Coast of Greenland from Cape York to Etah which they called piblokto and which he designated as a form of hysteria. Peary stated that he had never known a child to have piblokto, but that some of the adult Eskimos would have an attack every day or two, and that one day they had five cases. Concerning the attack proper, Peary spoke as follows: “The patient, usually a woman, begins to scream and tear off and destroy her clothing. If on a ship, she will walk up and down the deck, screaming and gesticulating, and generally in a state of nudity, though the thermometer may be in the minus forties. As the intensity of the attack increases, she will sometimes leap over the rail upon the ice, running perhaps half a mile. The attack may last a few minutes, an hour or even more, and some sufferers become so wild that they would continue running about on the ice perfectly naked until they froze to death if they were not forcibly brought back.” Peary goes on to say that when the attack takes place indoors, nobody pays much attention to it unless the sufferer should reach for a knife or attempt to injure someone. The attack usually ends in a fit of weeping, and when the patient quietens down, the eyes are bloodshot, the pulse high, and the whole body trembles for an hour or so afterward. It was also remarkable that the Eskimos dog suffered from a morbid condition by the same name. Peary stated that it did not seem to be infectious, though its manifestations were similar to those of hydrophobia.

For diagnostic purposes, Doctor Brill said he tried to ascertain whether these attacks of piblokto were accompanied by a loss of consciousness. Professor Donald B. MacMillan, an anthropologist, and one of Peary’s trusted lieutenants during the successful quest of the North Pole in 1908 to 1909, was certain that all of the cases he saw showed a loss of consciousness, and that they were all in a confused state. Thus, they were perfectly harmless when left to themselves, but showed a blind resistance if prevented from following out their individual vagaries. Granting this loss of conscious-
ness to be so, it would not simplify matters as regarded diagnosis. Loss of consciousness might be a concomitant symptom of hysteria or epilepsy. So far as could be ascertained, none of those afflicted ever showed a typical grand mal attack. On the other hand, everything pointed to hysteria. The disease was almost exclusively confined to the female sex: Professor MacMillian quoted Peary as saying that in twenty years he saw only one man who had what he thought was piblokto, and the disease was practically unknown in children. Of the twenty women aboard the "Roosevelt," eight had piblokto. The Eskimos themselves thought that the disease had something to do with the evil spirit, and for that reason they were reluctant to touch the afflicted during the attack. The only probable cause of this affection mentioned by Peary was of a psychogenetic nature. He said: "The immediate cause of this affection is hard to trace, though sometimes it seems to be the result of a brooding over absent or dead relatives, or a fear of the future." In other words, in the ultimate analysis, it was love and hunger. Professor MacMillian believed the attacks were caused by abuse. Most of the Eskimos who had this disease were of a jealous disposition. They either imagined themselves illtreated, or they actually suffered abuse at the hands of their husbands, who beat them with their fists. Many Eskimos were cruel to their wives. Speaking of the attacks, he said they reminded him of a little child discouraged and unhappy because it imagined that no one loved it nor cared for it, and therefore ran away. This plainly showed, Doctor Brill said, that as in civilized people, it was hunger and love—especially the latter—that played the great part in the causation of hysteria. It was also interesting to note that it was not the lack of the gross sexual, but the ungratified desire for love that was the determining factor.

In closing, Doctor Brill said that these attacks resembled the "running amuck" of the Malays, but that it was difficult to say whether there was really a total loss of consciousness or not. He saw no objection to calling such an attack a peculiar psychical manifestation, but he saw no reason why one should think that these attacks showed any resemblance to manic depressive insanity or to catatonia. There was absolutely nothing in these attacks to suggest these diseases.

Some Notes on "Transference" in Psychoanalysis.—Dr. Smith Ely Jelliffe read a paper on this subject, in which he said that as yet, the whole psychoanalytic situation, so far as successful therapy was concerned, was intimately bound up in transference, and one whose purpose it was to attempt to get at the causes for good or bad therapy, must needs view this situation as comprehensively as possible. Stated categorically and baldly, it might be said that without proper transference, a successful therapy for the psychoneuroses was impossible. In speaking of rapport or transference, it was well known that we were not dealing with any new phenomenon: it was older than the Mosaic law, and, like other old truths, it was constantly being stated and restated from epoch to epoch, in new forms and at recurring times with sharper and sharper differentiation. The psychoanalytic method fortunate-
of which Freud has been the first to offer a definite
deleted psychological interpretation. Due consideration is
given to the psychoanalytic method of investigation and
treatment, and the deficiencies and the errors of the
criticism which have been made of Freud's work.
While the impartial reader may not be able to either accept
or reject all of the views presented, he cannot but be
impressed by the fertility of the mind which has con-
sidered questions of mental health in such wide
scope. The author is an adept at making the data
of the patient's case and at giving the final interpre-
tation of the same. The author's mind is a
wealth of imagery, and the results of
Freud's theories which represent the most elabora-
tive attempt to produce a rational, practical psychology
as a form of fixation for the scientific treatment of
the neuroses.

Mind and Health. With an Examination of Some Sys-
tems of Divine Healing. By Edward E. Weaver, Ph. D.
Sometime Fellow in Clark University. With an Intro-
duction of Mr. Stanley Hall, Ph. D., LL. D.,
Professor of Physiology in the University
of Clark University. New York: The Macmillan Com-
pany, 1913. Pp. xv-500. (Price, $2.)

This book is written from the nonmedical standpoint, re-
viewing with impartiality the different theories of psy-
chological views on the mental and physical states
processes on the health of the individual, and discussing
at length the problem of Divine healing. The author
shows great versatility, and quotes extensively throughout the
work. In Freud's method of psychoanalysis he sees
that the medical profession should profit by the
philosophy and allied subjects, and credulously cites in-
stances of patients who suffered from embolism, and
pneumonia, whose lives were spared by their physi-
cians, but who cured themselves. He refers to
the influence of faith in Divine healing, and the
power of prayer of pastors, in one case "telepathically"
by absent treatment
when the patient was unconscious. The professed
aim of the book has been to further the adoption, by
the church, of the function of mental healing, advocating
the training of such individuals. By this
a great amount of valuable material is presented, the
prevailing atmosphere of religious mysticism, and credence
of the actuality of Divine healing detract from the
scientific value of the work.

The Relations of the Lachrymal Organs to the Nose and
Nasal Accessory Sinuses. By Prof. Dr. A. Onodi,
Director of the Phalinaerangium in the
University of Budapest. With Photographic Reproductions
in Natural Size of Forty-five Preparations. English
Translation by Dr. Dan McKenzie, London.

Professor Onodi's book is a monograph of 23 pages; it is
presented in the original German with translation into
both French and English. There is a good bibliography added, and forty-five reproductions of dissections, showing
that with care and attention to details the anatomy of the parts studied.
The question of the development of the parts, together
with operative relief for lachrymal obstruction, is carefully
considered. The translations make the book valuable for
those not using German. The English one faithfully
follows the original, while the French translator has seen it
omitted small parts of the text, without, however, vitiating
the meaning. The French text has a very considerable
number of typographical errors—due evidently to care
in an admirable manner the anatomy of the parts studied.
Professor Onodi has brought together the material on the lachrymal organs in
small compass and in a useful form.

Sterility in the Male and Female and Its Treatment. By
Max Hühner, M. D., Chief of the Genitourinary De-
partment, Harlem Hospital Dispensary, Formerly At-
tending Genitourinary Surgeon, Bellevue Hospital, etc.
(Price, $2.)
The author gives in his preface his object in writing the
book. First: "It will present the results of original and
systematic study on the subject of sterility, and
secondly, it will present a practical method of the treat-
ment of sterility in the male and female based upon a
scientific and accurate knowledge of the
anatomy and physiology of the
organs of reproduction."
He assumes that a postcoital examination of the
fluid in the cervical canal gives more precise information
than the examination of a condom specimen; and he
states that a precoital douche is useful in certain cases
of sterility to help to preserve the material or
spermatozoa. The statistics of the author's cases unfortunately
prove nothing. The effect of an alkaline douche causing the
secretion to become alkaline, and therefore prolonging the life period of the spermatozoa.

Insurance Medicine, Being Suggestions to Medical Exam-
ners. By Henry H. Schroeder, M. D., Medical Director,
Mutual Life Insurance Company of New York; Editor
Insurance Department, Medical Record. New York:
As the chapters of this book were running serially in the
columns of the Medical Record, the reviewer's thought
was that they were too valuable to be lost and were
worthy of presentation in more durable shape. The
experience of Doctor Schroeder as a life insurance ex-
aminer is a guarantee of the general correctness of his
findings and advice. The reviewer, however, would take
exception to one statement in the description of Heller's
test for the detection of albumin: "When albumin is presen-
t in small amounts, it is imperative for the tube to be set
aside carefully for at least fifteen minutes in order to get a
positive reaction with traces of albumin." In the
reviewer's experience, a fifteen minute lapse of time
would not have disappeared. The urine of all
be...
absence for thirty days from July 18, 1913, amended to read "thirty days' leave of absence from July 14, 1913."

United States Army Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Army for the week ending August 22, 1913:

Baker, C. R., First Lieutenant, Medical Corps. Detached from duty at Fort Jay, N. Y., on August 15th, and ordered to Fort Niagara for temporary duty. Beaven, C. L., First Lieutenant, Medical Reserve Corps. Ordered to Fort Hancock on August 28th for temporary duty. Blanchard, R. M., Captain, Medical Corps. Left Fort Leavenworth, G. N. on August 15th for temporary duty at Fort Niagara, N. Y., until October 1st. Carswell, R. L., Captain Medical Corps. Granted four months' leave of absence en route from the Philippine Islands. Connolly, F. B., First Lieutenant, Medical Corps. Granted leave of absence from duty at Fort Wainwright, Alaska, on August 15th, and will return to his proper station. Davis, A. D., Captain, Medical Corps. Left Fort Riley on August 16th on two months' leave of absence. Ferenbaugh, T. L., First Lieutenant, Medical Corps. Reports arrival at Fort St. Michael, Alaska, on July 28th. Graham, J. C., First Lieutenant, Medical Corps. Ordered to Fort Totten on August 28th for temporary duty. Gregory, J. C., Captain, Medical Corps. Left San Francisco on August 13th on three months' leave of absence (orders to Fort Screven). Kremers, E. D., Captain, Medical Corps. Left Department Hospital at Honolulu on August 5th on one month's leave of absence in the United States. Magee, J. C., Captain, Medical Corps. Granted two days' leave of absence. Meister, W. B., First Lieutenant, Medical Corps. Reports arrival at Fort Davis, Alaska, on July 31st. Mills, Raymond W., First Lieutenant, Medical Corps. Special Orders No. 171, dated July 24, 1913, pertaining to First Lieutenant, Medical Corps, revoked. Raymond W. Mills, First Lieutenant, Medical Reserve Corps, of his commission as an officer in the United States Army, has been accepted by the President, to take effect on November 20, 1913; leave of absence granted him in Special Orders No. 170, dated July 17th, 1913, under the War Department, is extended to and including November 20, 1913. Reasoner, M. A., Captain, Medical Corps. Granted leave of absence for twenty-four days. Russell, F. F., Major, Medical Corps. Relieved from duty at the Army Medical School and as curator of the Army Medical Museum, Washington, D. C., to take effect on or about October 15, 1913, and will then proceed to New York city and report to the commanding officer of the Medical Corps in that city. Shook, Jay R., Major, Medical Corps. Will proceed from Fort Logan, Colo., to Denver, to represent the Medical Department of the Army at the annual meeting of the Association of Militar Surgeons in that city. Vedder, Edward B., Captain, Medical Corps. Relieved from duty at the Rockefeller Institute, for Medical Research, New York, N. Y., effective October 1, 1913, and will proceed to Washington, D. C., and report for duty as assistant professor in clinical microbiology and bacteriology, Army Medical School. Waring, J. B. H., Captain, Medical Corps. Relieved from treatment at the Walter Reed General Hospital, District of Columbia, and given leave of absence from further duty at Fort Leavenworth, Kansas, and will proceed to Fort Logan, Colo., and report in person to the commanding officer of that post for duty. Whitemore, Eugene R., Major, Medical Corps. Relieved from duty as attending surgeon, New York, N. Y., effective on October 1, 1913, and will proceed to Washington, D. C., for duty as professor of military and tropical medicine, Army Medical School. Wickline, W. A., Captain, Medical Corps. Left Walter Reed General Hospital on August 8th on one month's leave of absence.

MARRIAGES.

Morgan—Lindemuth. In Reading, Pa., on Thursday, August 15th, Dr. David W. Morgan, of Auburn, and Miss Edna C. Lindemuth.

Died.

Blount.—In Evansville, Ind., on Saturday, August 16th, Dr. Joseph F. Blount, aged eighty-six years.

Boden.—In Oneida, N. Y., on Saturday, August 16th, Dr. Edwin R. Boden, aged fifty-four years.

Davis.—In Camden, N. J., on Sunday, August 17th, Dr. William Albert Davis, aged sixty-two years.

Ferris.—In New York, on Thursday, August 21st. Dr. Cleaveland Ferris, aged thirty-five years.

Fisher.—In Zion, Pa., on Sunday, August 24th, aged sixty-seven years.

Fitch.—In Glacier Park, Mont., on Tuesday, August 19th, Dr. Calvin Ingram Fletcher, of Indianapolis, Ind.

Gayley.—In Hazelton, Pa., on Saturday, August 16th, Dr. William C. Gayley, aged fifty-four years.

Greene.—In Dayton, Ohio, on Sunday, August 17th, Dr. Duff W. Greene, aged sixty-two years.

Guernsey.—In Los Angeles, Cal., on Thursday, August 14th, Dr. George S. Guernsey, aged ninety-one years.

Huck.—In Baltimore, Md., on Wednesday, August 13th, Dr. John George Huck, aged sixty-four years.

Ladd.—In Geneva, N. Y., on Friday, August 15th, Dr. George Ladd, aged sixty-two years.

Ladd.—In Rhinebeck, N. Y., on Sunday, August 17th, Dr. E. H. Ladd, aged sixty-five years.

Lord.—In Essex, N. Y., on Saturday, August 16th, Dr. John Ladd, aged sixty-four years.

Middletown.—In Middletown, N. Y., on Thursday, August 21st, Dr. Anson D. Middletown, aged seventy-one years.

Miller.—In St. Paul, Minn., on Tuesday, August 12th, Dr. Clinton Clarence Miller, aged fifty-nine years.

Overstreet.—In Dayton, Ohio, on Friday, August 15th, Dr. James E. Overstreet, aged forty years.

Ryder.—In Oxford, Mass., on Wednesday, August 20th, Dr. Emily Brainard Ryder, aged eighty-four years.

Swigart.—In Hastings, Neb., on Tuesday, August 19th, Dr. Henry M. Swigart, aged sixty-four years.

Turner.—In Washington, Conn., on Saturday, August 16th, Dr. Henry Cushman Turner, of Brooklyn, N. Y., aged sixty-eight years.

Vander Veen.—In Grand Rapids, Mich., on Saturday, August 16th, Dr. Christian Vander Veen, aged forty years.

Van Reimpst.—In Saranac Lake, N. Y., on Thursday, August 21st, Dr. Theodore Schaeckens Van Reimpst, of New York.

Wells.—In Binghamton, N. Y., on Thursday, August 21st, Dr. Emily H. Wells, aged seventy-one years.
Orthopedics in General Practice.*
Emphasizing the Importance of Early Diagnosis.
By Charles Ogilvy, M.D.,
New York.

The general practitioner is the first to be consulted about acquired deformities, and it is therefore of the greatest importance to him that he recognize these conditions in their earliest incipiency. Acquired deformities, if recognized in their earlier stages, can be intelligently treated by the general practitioner. If this were done many deformities which would otherwise develop would be prevented, and we should not then see so many cases which have gone on to the later stages of development. These are much more difficult to treat, and they present the marked deformities only because they have not been previously recognized. Associated with these deformities are many indefinite pains which are referred to the feet, to the knees, to the lumbar spine, and to the dorsal spine, and have special significance as regards standing and walking.

That you may be enabled to recognize a number of the conditions which are responsible for these indefinite complaints, and that you may be able to obtain some practical information that will be of material value to you in your practice, is the object of this paper. The subjects which we shall at this time consider are those of: 1. Weak feet. 2. Weak anterior arch. 3. Hallux valgus. 4. Anteroposterior postural deformity.

1. Weak Feet.

Note the term "weak feet," and not "flat feet"; for the condition of weak feet should be recognized long before the flattening or lowering of the long arch of the foot has developed. The importance of the care of the feet cannot be overestimated. Seldom is a weak foot recognized before flattening has developed, and a long train of symptoms have followed in its wake. The general practitioner is constantly consulted for indefinite aches and pains of the feet and legs, and, too frequently, indeed, are such complaints regarded as symptoms of chronic rheumatism—whatever that may be.

If a patient complains of continued discomfort or constant pain in the feet or ankles, and in these joints only, from a period of time ranging from weeks to months, with a negative history of any other joint involvement, almost invariably will you find that the trouble is caused by weak feet, and an examination with this view should in every case be made. Do not examine such patients in a sitting posture with the feet raised toward you. The feet were made to stand upon and to walk upon, and therefore they should be examined while so functioning. Here we learn the importance of the meaning of a correct relationship of the foot to the leg in its capacity of a body weight bearer. The body weight normally passes through the centre of the knee joint, a little to its inner side, down the leg through a line represented by the crest of the tibia, through the centre of the ankle joint and over the dorsum of the foot to the second toe. When we find the foot everted (Figs. 1, 2, and 3) (rolled outward) this relationship is immediately changed, and the body weight no longer passes over the dorsum of the foot to the second toe, but down to the inner side of the foot, to a point corresponding to the astragalo-scaphoid articulation. Just as soon, then, as this abnormal relationship is established, just so soon is there demanded of the long arch of the foot the sustenance of the body weight bearing down upon its highest point. It is then simply a matter of time before it gradually gives way. Symptoms of discomfort, and subsequently pain, develop (sometimes associated with backache), and later there presents itself to us a typical flat foot (Fig. 4). This could have easily been prevented by the recognition of the eversion and its correction.

Treatment. The proper treatment of weak feet, or even flat feet, is by no means an insertion of plates or foot supports which the patients are usually advised to procure at some near by shoe store. Such arch supports do more harm than good. The proper foot plate is one which supports the foot anteroposteriorly, and also laterally when the foot is performing its function of weight bearing. Such a plate can only be made from a plaster model of the foot; which plaster cast is further remodeled to complete the correction of the deformity desired. Furthermore, the employment of any arch support is detrimental to the well being of such feet unless the eversion, which has already been noted and which is always present, is first corrected. This is really the most important point in the treatment of weak feet. It can be corrected and controlled by elevating the inner side of the heel of the shoe and extending the heel forward on the sole some three quarters of an inch. This should be done in every case.

In the milder cases this alone will be found all that is necessary, provided the shoe chosen is built on proper lines—with a straight line on the inner
side of the sole, etc., to obtain proper foot balance. In addition, we must, by foot exercises, strengthen the muscles which control the position of the foot in its relation to the leg, and so enable us to retain our corrected position. It is difficult to control some patients in this regard, and one sometimes has these patients returning after two or three years of such treatment with the criticism that though the symptoms have been relieved, the correction of the position of the foot cannot be maintained and will relapse immediately the plate and shoe are removed. For this reason the writer has advised an operation by means of which a fixation of the astragaloscaphaloid joint is procured by an arthrodesis. At the same time the direction of the astragalus is corrected, and inversion of the foot obtained, and a subsequent flattening of the arch, as otherwise follows, is prevented. (Fig. 5.) In none of the cases operated on has it been necessary to use plates subsequent to the operation. I wish to emphasize the importance in performing this operation of changing the direction of the head of the astragalus from an inward to an outward position.

Operation.—An Esmarch bandage is applied immediately above the knee joint. This is not removed until the complete dressing is applied after the operation has been performed. A curved incision is made from above downward, immediately over the astragaloscaphaloid articulation. The incision is made through the skin and subcutaneous tissue, down to the astragaloscaphaloid ligament, and through this ligament to the joint itself. The head of the astragalus is now brought prominently into the field of operation by forcibly evertting the foot. The articulating surface of the astragalus is removed, and likewise the articulating surface of the scaphoid. The field of operation is then irrigated with a normal saline solution, and the wound closed with a deep interrupted and continuous superficial catgut sutures. Generous shaken out gauze dressings are applied, and the forefoot is drawn inward and downward in marked inversion. Plaster of Paris bandages complete the dressing, which is allowed to remain on for five weeks. (Fig. 6.)

2.—Weak Anterior Arch.

A patient consults you with the following symptoms: A pain of severe character referred to the head of the second, third, or fourth metatarsal bone, frequently very severe; symptoms coming on suddenly while walking, and necessitating removal of the shoe and rubbing the foot. After this massage the pain is relieved; the foot is replaced in the shoe, and comparative comfort is established until, at some subsequent date, the same symptoms recur. In the meantime the pain is not entirely relieved, but is not sufficiently severe to demand a call on the physician.

The diagnosis of this condition, which is that of anterior metatarsalgia, is not difficult. (Fig. 7.)

The cause is that the anterior arch breaks down and allows the heads of the metatarsals to drop; thus straining the ligaments and stretching the tissues. Contrary to what is usually done in these cases, the arch should be supported by a pad of felt, one and a half inches wide by two inches long, which is strapped in position over the heads of the metatarsal bones. This reestablishes the natural position of the forefoot and immediately relieves the symptoms. Permanent support of this kind may be built within the shoe.

3.—Hallux Valgus.

So often is hallux valgus associated with the conditions already mentioned that I wish to emphasize the importance of its correction before one can obtain good results in the treatment of either weak feet or weak anterior arch. (Fig. 8.)

The reason of this is obvious, as the direction of the great toe is changed from an anterior to an internal direction, with an associated broadening of the forefoot, due to the head of the metatarsal bone of the great toe being driven outward as the point of the great toe is brought inward. As long as this relationship is allowed to remain it is impossible to permanently strengthen the anterior arch. This is due to the fact that the direction of the weight strain through the foot is altered. For this reason it is essential, for the proper care of the foot, to have a shoe with a straight inside sole, and not one which is pointed and crowds the great toe toward the median line.

Treatment.—There is but one satisfactory line of treatment for hallux valgus, and that is operative. The operation consists of making a semicircular incision around the prominence, with the convexity of the curve anteriorly. The flap of the skin is laid back, exposing the bursa, which is removed. When this is removed the metatarsophalangeal joint is exposed, and the head of the metatarsal bone chiseled away. This wedge of bone which is removed has its base toward the inner border of the foot, and its apex extends directly across the joint to its opposite side. Upon the direction of this bone incision will depend the position of the great toe when the operation is completed, and therefore it will vary—being dependent upon the degree of the original deformity. The incision is closed by deep interrupted and superficial continuous catgut sutures. A dressing is applied which holds the great toe in its corrected position, and a plaster of Paris bandage guarantees secure fixation in this position.

The results of operation are most satisfactory, and, provided the foot is subsequently properly shod and firmly supported, one can promise not only relief of the symptoms complained of, but also a prevention of any subsequent trouble of a similar nature.

Intoeing.

So frequently are you consulted about the intoeing of children that a word on this subject will not be amiss. The natural position of the foot in walking is not that in which the toes point outward, but one in which the foot is directed straight forward with a slight inclination to intoeing. This is the position of strength, and it denotes a strong foot and ankle. Walking with the toes turned outward tends to weakness, rather than strength, and should not be encouraged. A moderate degree of intoeing on the other hand, should rather be encouraged than discouraged, as a child who toes in is assured of a strong foot without the fear of any subsequent flat foot.
4.—Anteroposterior postural deformity.

The subject of anteroposterior postural deformity is one which, up to the present time, has not been sufficiently emphasized. (Figs. 9 and 10.)

If we could but have these cases recognized early we would not see so many of the marked deformities of rotary lateral curvature which are constantly being referred to us. The class of patients which are here referred to are characterized by very definite and constant peculiarities. They are those who lack muscle tone. These are the children whom you see lagging behind in their romp and play, tiring very easily, refusing to continue the game with the other children, hanging back when any active exercise is being enjoyed. They run clumsily, they walk with an ungainly gait—with rounded shoulders and head forward. In the standing posture the abdomen is prominent, the shoulders are rounded, the chest is sunken (retracted), and the head is protruded. When sitting down they may best be characterized as those who "flop over," either upon their book or upon the table before which they are seated.

The symptoms complained of in such cases are very indefinite. Often they complain of a tired feeling in the back, and sometimes in the lumbar region. These pa-

**Fig. 2.—**The feet of a child four years of age, who complained of being unable to walk without tiring, and had the general symptoms as described in the text.

**Fig. 3.—**F. P., aged twelve years; typical weak feet before operation.

**Fig. 4.—**Showing marked eversion with subsequent typical flat feet.

**Fig. 5.—**F. P., showing postoperative result. The patient broke the record for high jumping in public school sports seven months after operation.

**Fig. 6.—**Postoperative dressing for weak feet.

**Fig. 7.—**Weak anterior arches. Note the bulging of the forefeet and the cramping of the toes.

tients are very often subject to weak feet. They are pale and languid. Poor appetite and general debility complete the picture. Tonics are prescribed and prove of little avail. Such a condition is found more frequently among girls than boys: the reason for this being that boys are naturally more inclined to the muscular activities of outdoor sports and games.
The difficulty of diagnosis from the indefiniteness of the symptoms is counteracted by the ease with which the condition is recognized when the clothing is removed and the patient is made to stand before the examiner. One recognizes at a glance the abnormal posture, and the diagnosis should immediately be made. (Figs. 11, 12, and 13.)

There is no structural change in this deformity, mark you. The position is entirely due to habit. This postural deformity can be voluntarily corrected by the patient. The condition can be cured by properly directed breathing exercises, light calisthenics, and good hygienic and dietetic care.

Why then, you ask, should so much emphasis be laid upon a condition which can be so easily corrected and in which there is no structural deformity. And in the answer to this question lies the salient point of importance in the recognition of these cases at this stage of development. If proper treatment is not advised or followed we see, in such cases, slight lateral deviation of the spine gradually develop, which, at first, is hardly recognizable, but which slowly increases.
And with this we find an associated rotation of the spinal column. With this lateral deviation and rotation of the vertebrae a change takes place in the contour and structure of the vertebrae. These are no longer symmetrical, but change in form to a greater or less extent, depending upon the length of time and progress which the deformity has made. This we term rotary lateral curvature of the structural type; by which we mean that there has developed a fixed rotary lateral curvature which is impossible to correct by any voluntary muscular effort of the patient. The symptoms of this condition are much more severe than those of the anteroposterior postural deformity cases. The treatment is also much more difficult, and the prognosis regarding deformity much more grave. Thus you see how important it is to prevent such a sequence of events. Many cases of structural rotary lateral curvature could readily have been prevented had the first symptoms of anteroposterior postural deformity been recognized.

40 East Forty-first Street.

VACCINE TREATMENT OF TYPHOID FEVER; REPORT OF CASES.*

By B. M. Randolph, M. D.,
Washington, D. C.,
Professor of Materia Medica and Therapeutics, Medical Department of George Washington University.

I think it has been pretty well demonstrated, first by Dr. Sterling Rufin, of Washington, D. C., that cases of typhoid which have an unduly prolonged febrile period (the cases of delayed recovery) are promptly brought to a favorable termination by the use of the vaccine. It seems, too, that the vaccine is very effective in cutting short relapses, though the varying duration of relapses makes it more difficult to assign the subsidence of the fever to the treatment. This is one of the questions that can only be answered by the controlled observation of a large number of cases. I have used the vaccine in several cases of relapse and delayed convalescence, with what appeared to be prompt and satisfactory results. I do not include these in this report, except to furnish examples. It was my original purpose to select for the experiment only severe cases, seen early in the disease. I have adhered to the factor of severity, but have employed the vaccine in a number of cases where the disease had been established for two weeks or more. This is because hospital patients come under observation at a much later date than those seen in private practice. Often their treatment has been undertaken at home, where they have become so ill that the facilities for dealing with them are overtaxed, and they are then brought to the hospital. Ordinary mild cases have been excluded, and it may be assumed that every case here reported is one of severe intoxication, unless the contrary is stated.

The cases fall naturally into four groups:
(a) Those in which the treatment was begun early in the infection.
(b) Those in which the patients have been ill ten days, or more.
(c) Terminal cases.
(d) Cases of relapse or delayed resolution.

Of the last two groups examples only will be shown.

Case I. Mrs. A. G. (George Washington Hospital, 11,844); white, aged twenty years, married. Had taken to bed two days before admission, but had had headache and malaise for a week or ten days previously. On admission temperature was 103.4° F., pulse 128, respiration 38. Typical picture of severe intoxication; great apathy; muscular tremor on motion. The Widal test was positive on the seventh day, and 200,000,000 typhoid bacilli were injected subcutaneously in the arm. Three other injections were given on the ninth, thirteenth, and seventeenth
days respectively, the dose being increased by 200,000,000
at each injection. Patient also had sponge baths during
the first week of her stay in the hospital. The tempera-
ture became permanently normal after twenty-one days' stay
in the hospital. The patient was slow in regaining her vigor, and remained in the hospital forty-three days.
Several weeks after returning home she had, after exert-
tion, a sharp attack of syncope. I mention this to show
the severity of the intoxication.

Case II. R. H. (George Washington Hospital, 15,135); white, male, aged nineteen years. Admitted on fourth day
of disease, after five days of prodromes, in a delirious
state, with all the evidences of an intense typhoid intoxica-
tion: dilated pupils, tremor, hebetude alternating with de-
limium; a profuse eruption over entire trunk almost as
thick as that of measles; moderate abdominal distention
with tenderness; scanty urine; seven or eight stools daily:
pulse dicrotic, temperature 104° F. pulse 96, respiration 28.
Widal test was negative. Owing to some confusion in the
communications with the laboratory, a positive blood cul-
ture was not obtained until the patient had been in the hos-
pital eleven days. At the beginning of the administration
of the vaccine there had been no improvement in his condi-
tion. Through a misunderstanding of an order, the first
dose of bacilli was twenty-five million, instead of 250 mil-
ton. 250 million was injected on fifteenth, eighteenth,
twenty-first, and twenty-fifth days. Marked improvement,
consisting in an improved character of the pulse, and sub-
jective sense of well being, while an access of appetite be-
gan on the sixteenth day. The total febrile period in the
hospital was twenty-seven days; rapid convalescence. In
addition to the vaccine, small amounts of whiskey were
given during the period of dicrotism of the pulse. In hospital
thirty-five days; febrile period twenty-four days.

Case III. L. B. (Garfield Hospital, 29,535); colored, female, aged nineteen years. Admitted on ninth day of
the disease with severe typhoid intoxication: headache,
nausea, anorexia, diarrhea, abdominal distention, with se-
vere pain and tenderness; very apathetic; complained con-
stantly and bitterly during the first week of her stay in
hospital. Widal test positive on eleventh day. One third
billion of bacilli injected on the thirteenth day, and two
thirds billion on the fifteenth, seventeenth, nineteenth, and
twenty-first days respectively. Marked subjective improve-
ment after the second injection, which continued through-
out. The patient changed from a very querulous person
to a contented one. Temperature became normal after
she had been in the hospital fourteen days. Out of bed
in twenty days, and on house diet in twenty-two days.
During convalescence she began to have a slight afternoon
rise of temperature, which was found to be associated with
the physical signs of an apical tuberculosis. In hospital
thirty-two days.

Case IV. M. L. (Garfield Hospital); colored, female,
aged thirty-six years. Case of severe typhoid intoxica-
tion; condition too apathetic to obtain history. Admitted
on seventh day of the disease. Widal test positive on
fifth day after admission. One third billion bacilli given
on the thirteenth day, and two thirds billion on the six-
teenth, nineteenth, and twenty-fifth days respectively.
Pro-
nounced subjective improvement followed the second dose:
rapid recovery. Duration of febrile period in the hospital
twenty-three days; in hospital thirty days.

Case V. R. M. (Garfield Hospital); colored, male,
aged twenty-five years. Admitted to the hospital on sixth day
of the disease with severe toxic symptoms: great disten-
tion and severe and persistent abdominal pain and tender-
ness; nausea, anorexia and profuse diarrhea; delirious;
pulse dicrotic. Complained of numbness of the right
hand; profuse sweats day and night; annoying cough.
This seemed to me to be undoubtedly one of those cases
associated with extensive ulceration of the colon. Widal
test positive on seventh day. One third billion bacilli
given on eighth day, one half billion on eleventh day, and
two thirds billion on the sixteenth, nineteenth, twenty-
second, and twenty-fifth days respectively. The only other
treatment, beside good nursing, was daily colon irriga-
tions, small doses of turpentine while the distention lasted,
and small amounts of whiskey while the pulse was bad.
The temperature became normal on the twenty-sixth day,
twenty days after admission; total stay in the hospital
thirty-seven days. During convalescence a painful local-
ized periostitis developed on the extensor side of the right
forearm, just above the wrist. This vanished in twenty-
four hours under the application of a fly blister. (No chart.)
Case VI. P. T. (Garfield Hospital, 27,617); colored, female, aged twenty-six years. Admitted on fourteenth day of the disease. Brought in on stretcher in a delirious condition. History of onset with chills, fever, headache, anorexia; cough for the preceding four or five days; urine contained albumin, and hyaline and granular casts. Case complicated by gonorrhea. Widal test positive on sixteenth day. On seventeenth day 200 million bacilli were given 400 million on the twentieth, 600 million on the twenty-fourth, and 800 million on the thirtieth days of the disease. This patient gave enthusiastic testimony to the improvement that followed the second dose, though she dreaded it because of the sore arm that followed the first. She described herself as "feeling fine" during the remainder of her stay in the hospital. Duration of the febrile period in the hospital twenty days; in hospital thirty-three days.

Case VII. S. T. (Garfield Hospital); colored, male, aged twenty-six years. Admitted on fifteenth day of the disease. Moderately severe intoxication. Widal test positive on eighteenth day. On the same day two billion bacilli were given, which was repeated on the twenty-sixth and twenty-seventh days. At this time my service in the hospital terminated. Through the courtesy of my successor on the service, Dr. J. Dudley Morgan, I was permitted to continue with the case. The supply of vaccine at the hospital was permitted to run out, and owing to my not giving the case as close personal supervision as I should have done, ten days elapsed during which the patient received no vaccine. The temperature, which had been steadily declining, remained stationary a few days, and then began to rise. Two thirds billion bacilli were again given on the thirty-third and thirty-sixth days, and one billion on the thirty-ninth and forty-third days. The temperature became normal on the forty-first day. The rise on the forty-second day was coincident with an accumulation of feces in the lower bowel. After a colon irrigation, which was followed by two liberal bowel movements, it dropped promptly, and did not rise above normal thereafter. Total febrile period in the hospital twenty-six days.

Case VIII. M. N. (Garfield Hospital, 27,724); colored, female, aged twenty-one years. Admitted to the hospital in advanced stage of the disease. Brought in on a stretcher; delirious, so that restraint was necessary to keep her in bed. Widal test positive on third day after admission; 200 million bacilli given on fourth day and continued in increasing doses (see chart). Death occurred after the patient had been in the hospital eighteen days. There was no apparent effect from the vaccine. I am in doubt whether this was a pure typhoid infection, the temperature suggesting that there may have been some other factor present.

Case IX. M. W. (Garfield Hospital, 27,685); white, female, aged twelve years. Admitted seventh day of disease. High temperature, rose spots, enlarged spleen; the child did not seem very ill. Her serum gave the swiftest and most complete clumping and immobilizing reaction I have ever seen. Five days after admission her temperature became normal, where it remained a week. During this time she was permitted to sit up in a chair. On the seventeenth day the temperature began to rise. We put her back in bed, and waited until the twenty-fourth day to assure ourselves that the fever was not a transitory recrudescence. On the twenty-fourth day she received 200 million bacilli, and on the twenty-sixth day her temperature was again normal. The same dose was repeated on the twenty-seventh day, and the child had no further interruption to convalescence.

Case X. A plethoric woman was brought into the hospital in the beginning of the third week of the disease, with an overwhelming typhoid intoxication, accompanied by double pneumonia. An unfavorable prognosis was given the first time she was seen. Typhoid vaccine was employed in full doses, without producing the slightest effect, either in the way of reaction or improvement. Death occurred after nine days in the hospital. As the chart shows nothing of interest, it is not submitted.
I have also used the vaccine in two cases of typhoid brought into the hospital in a moribund condition. Further than a rise of temperature following the injection, there was no result, the patients dying promptly, as would have been otherwise expected.

*Vaccine.* The vaccine used in these cases was the same as that used by the United States Army for prophylaxis against typhoid fever, and was supplied me through the courtesy of Major F. F. Russell. I am also indebted to Major Russell for valuable advice on the administration of the remedy. The vaccine is put up for hypodermic injection in one c. c. ampoules, each containing one billion bacilli. It will be easy to interpret the dose entries on the accompanying charts by estimating one billion bacilli to each fifteen minims.

*Dose.* It will be seen that there is considerable variation in the dose and intervals of administration. This is due to the fact that I was trying out the remedy, in order to find the best method of giving it. In the more recent cases I have begun with one third billion bacilli, given a second dose of two thirds billion, and repeated this dose two to four times, until the temperature was normal. I have generally employed a three day interval, but am not convinced that a two day interval would not be better. I hope to work this question out in the future.

*Reaction.* The local reaction is about the same as the average local reaction seen with the prophylactic injection. There is a red, bluish white area about the size of a quarter of a dollar, accompanied by some induration, pain, and tenderness, and a slight aching motion. It has never been greater, and often less than this. The inconvenience is insignificant, passing off in twenty-four hours, and is generally not alluded to by the patients, unless they are asked about it. A febrile reaction is not produced in the height of the disease, nor is there any added malaise caused at this stage by the injection. As the temperature begins to decline, there follows the injection, usually a sharp increase that lasts from twelve to twenty-four hours. This is followed by a further and somewhat more precipitate decline. The cases of delayed convalescence and relapse have exhibited a much sharper reaction, both local and general, to even smaller doses of the vaccine than have those in the acute stage of the primary infection. In my judgment this dispenses of the fear that we may add to the toxic state by giving the vaccine in the acute stage.

*Diagnosis.* With the expectant and symptomatic treatment of typhoid fever that has prevailed, the practical importance of an early and positive diagnosis has not been very great. If, however, we are to employ a specific immunizing remedy, the diagnosis must be established without question before the treatment is instituted. If it should be established that the vaccine treatment is effectual, and the more so, the earlier it is begun, the importance of the earliest possible diagnosis becomes imperative. The Widal reaction, upon which the positive diagnosis has rested for the past fifteen years, is a fairly satisfactory criterion under expectant methods of treatment. We rarely get a positive Widal test before the seventh day of the disease, and it may be delayed till the twentieth day, or longer. McFarland, from the analysis of a large number of cases, places the average time of its appearance at the eleventh to twelfth day. In blood culture we have a means of establishing the diagnosis in the first week, and at the same time of differentiating it from paratyphoid organisms without repeated observations. If we are to use specific immunizing treatment in this disease it will be necessary to resort to a routine blood culture method of diagnosis, rather than to wait for the Widal reaction.

One word concerning the technic of procuring blood for culture purposes. Physicians seem to regard it as a formidable procedure, and are apt to refrain from undertaking it. When they do undertake it they often impress the idea of a major operation on the patient and his family, and the latter are alarmed by the elaborate preparations and the apparatus assembled. This is unnecessary. With ox bile as a culture medium, from two to five c. c. of blood is all that is required. An ordinary all glass hypodermic syringe, with a sharp needle from three quarts to one inch long, is needed. A constricting bandage above the elbow, and iodine sterilization of the skin over the vein, complete the preparation, except boiling the syringe. The requisite amount of blood can be withdrawn from the vein with exactly the same amount of inconvenience to the patient that is associated with giving an ordinary hypodermic injection. A little more skill is needed to insert the needle into the lumen of the vein.

*Duration.* The duration of the disease in the cases here reported is estimated from the day the patient took to bed. While, properly speaking, the onset of the disease is earlier, patients are so vague about the duration of the prodromal period that little reliance can be placed on their statements regarding it. The time of taking to bed can generally be exactly determined, though even about this very sick patients are often inaccurate.

*Diet.* These patients, on admission, have been started on a liquid diet consisting of milk, albumen water, and broths. I always make it a point to ascertain whether a patient likes milk, and whether it agrees with him in health. If this is not the cause, milk is not given. Buttermilk is often substituted with advantage. I begin to increase the diet as soon as the patient asks for more, commencing with toast, and gradually adding eggs, cereal, ice, junket, ice cream, baked apple. Oranges are given in moderation throughout the illness if the patient desires them. I have made no effort to feed on the basis of caloric estimates, having found that there is generally much difference between what is written on the bedside notes and what a very ill patient will eat and digest. I have found that, within reasonable limits, the patient's preference and appetite is the most satisfactory guide in feeding.

**Conclusions.**

As to the conclusions to be drawn from my observations, it is difficult to make a satisfactory statement. The number of cases reported is too...
small, and the manifestations of this disease too irregular, to permit of a final opinion. Satisfactory conclusions can only be drawn from a comparison of a large number of carefully studied cases treated by vaccine with a similar number of like cases not so treated. I may say, however, that I have at this time a strong clinical impression that the vaccine treatment has a beneficial effect in the acute stage of typhoid, and that this effect is better the earlier its administration is begun. This impression is founded on two things—first on the almost invariable testimony of the patient that he feels better. If this were purely psychic cooperation, it would manifest itself after the first injection. As a matter of fact, it has always come after the second. The patient in Case VI, who gave the strongest testimony to the improvement she felt, opposed the second injection, because of the soreness occasioned by the first. In the second place, it has seemed to me that defervescence has proceeded more surely and rapidly than with cases not so treated. Cases I, III, IV, and V, those in which the treatment was instituted fairly early in the disease, all became afebrile in twenty-five days or less from the onset of the disease. Cases I to VI became afebrile in nine to eighteen days after the treatment was begun. It will be offered that the normal duration of typhoid is from three to four weeks, and that a similar course would have been followed by these cases without the vaccine. In my experience the cases that run a three to four weeks course have been the mild ones; the severe intoxications rarely terminate so soon, and are more apt to run a febrile course of from five to seven weeks. All of my first six cases were severe, and in none of them would one have felt reasonably sure of a favorable outcome. Cases I, II, and V looked especially grave.

Case VII presents some interesting points for speculation. In a case of two and a half weeks' standing the vaccine was begun. Typical reactions followed the injections, as we saw in other cases late in the disease. There is a rapid tendency to defervescence, beginning after the second dose. The day after the third dose the minimum temperature reaches normal. The administration is interrupted for ten days. The temperature ceases to decline, and after five days begins to rise. What appears to be a mild, but typical, relapse appears to be instituted. The vaccine is resumed, and after three doses the defervescence is complete. Three questions present themselves:

1. Is this an ordinary relapse, presenting a temperature curve that was unaffected by the vaccine?
2. Did the vaccine produce the first decline in the temperature, and did its discontinuance account for its recrudescence?
3. If no vaccine had been given, would the temperature fall of the twenty-fourth to twenty-seventh days have been absent, and the defervescence have continued regularly to the time the disease finally terminated (forty-first day)?

Any one of these is a possibility, and an attempt to decide on which is correct would be guesswork. This case is the only one in which a relapse occurred where the vaccine had been used previous to the relapse.

Twentieth and P Streets, Northwest.

The Foundation of Education.

A Suggestion to Those Having Authority.

By Henry Jones Mulford, M.D.,
Buffalo, N.Y.

Never before has the educational cauldron been in such a turmoil; never before has the pot contained such a seething, bubbling, boiling, incongruous mass. Every passerby tosses something into it, hence the "double, double toil and trouble"; the uneasy mass has no opportunity for resolving itself into something definite, something worth while. Each addition but adds to the complexity, thereby increasing the agitation and delaying the termination of the process. Is it not too bad that the cauldron does not boil over, and, in so doing, boil itself dry? For, if a new start might be made with a clean pot, putting into it only selected materials, the resulting broth would be, not only palatable, but rational. It is with soup as it is with houses, the foundation is the main thing.

And so it is, too, in the matter of education, the foundation is the main thing. Of the structure reared by education the foundation is more important than the superstructure, for the strength of the superstructure depends upon the strength of the foundation. If the foundation is not carefully laid the superstructure will be a poor thing, wobbly and insecure, swayed by every passing breeze.

Now, we all know that education has to do, primarily, with the brain; that all education is brain education. The brain, of a truth, is the all of man: his past, his present, and his future; within this small mass of living tissue, weighing three pounds, more or less, are contained all of man's achievements, not only that which he has accomplished, but, also, that which he is to accomplish. It will be very obvious here, unless one possesses the mentality of an idiot, that the brain is an organ of very great importance. If the brain is the seat of education, then it is in the brain that the foundation of education must be laid; and it is the laying of the foundation that determines the strength of the brain, the value of the brain to the individual, and the value of the individual to the world.

And this foundation, this wonderful thing that is to lie at the bottom of each human brain and determine what the individual is to be, how shall it be fashioned? Shall there be just one general plan according to which all individual foundations are to be laid down? or shall there be a separate plan for each individual structure? That is, shall our children be dumped into a common hopper and ground out all alike, as sausages are ground out? or, shall we take each one by himself and develop his own individuality? There is danger in each method, even more, perhaps, in the latter than in the former; but, even with its greater menace, the last would seem to be the better one to follow. The fault of the first lies in the possibility that the individual would suffer from repression, that he would not attain to full development; the fault of the second, in the possibility of overdevelopment, of too much individuality. We surely need individuality in this world, and we need to encourage it; but, while we need to encourage it, we must not exalt it. If the individual is retarded there is no progress;
if he is urged beyond his powers he either breaks down or gets beyond his own control. Retarded progress, through a slowing of the machinery, may be remedied, but an absolute derangement of the mechanism completely shuts off all advance.

It is obvious, then, that all education must be individual, for no general plan can be adapted to individual variation; there are as many educations as there are individuals. Each foundation, laid within the individual himself, must fit the requirements of that individual, but it must follow rational lines. We must adjust to the individual, but we must not allow the individual to dominate. He must be neither underdeveloped nor overdeveloped; stupidity must be avoided as well as exaltation. The laying of an individual foundation, therefore, is no small task. The brain of man is a highly specialized organ which has developed in its own peculiar manner, and, in laying plans in regard to it, the manner of its development must be considered. It is only through a knowledge of brain evolution that we shall be able to understand individual variation.

"The brain is a highly specialized organ which has developed in its own peculiar manner." I repeat this, for therein lies something of our argument. In considering foundations we have to go to the bottom of things, to the beginning, and, this is especially the rule in matters pertaining to the brain. In order to understand the human brain we must begin at the beginning of that brain; but there is only one way of getting at its beginning, and, that is through evolution. The evolutionary history of the brain gives us the hint for the proper conduct of modern brain education. In tracing this history step by step, through one long epoch after another, we learn how the brain of man has grown, and how its many sided function has developed.

The human brain has to do with man, it is the organ of control; it is the centre for all nerve impulses, sensory, motor, and intellectual, and is composed of two kinds of brain tissue, gray and white. The gray substance, the cortex, is a cellular mass covering the surface of the brain, and is the active portion; the various "centres" controlling the body functions being located therein. This cortex is about one eighth of an inch in thickness, and, so far as weight is concerned, is but a small proportion of the brain mass. The entire brain weighs three pounds, more or less, the central mass composed of the white fibres which conduct the nerve impulses, making up the greater part of it. If the surface of the brain were just smoothly round, like that of a ball, there would be comparatively little of the gray matter. Its development would be limited, for the unyielding bony walls of the skull would not permit its further spread. But Nature has met the situation very cleverly; more cortex has been needed in the man brain and more cortex has been provided, in spite of limiting bony walls. The demand for more of the gray matter has caused the surface of the brain to develop into folds, known as convolutions, these convolutions being separated one from the other by fissures, more or less deep. In its development the gray matter has, as it were, dissected out these convolutions; dipping down from the surface, it covers every side of each convolution to the depth of the surrounding fissures. This arrangement has increased the area of this vital portion of the brain substance many fold, and has made the man brain possible.

A moment ago I stated that the centres of control were situated in the cortex. So well do we know this that we can point out the greater number of these centres. The centres for the special senses, smell, taste, hearing, sight, and tactile sensation, are well known, as are, also, the motor centres, those controlling muscular action. The intellectual centres cannot be so readily located, as must be obvious; but, although there is some doubt in regard to them, we have well founded suspicions as to where they are situated.

Now, it seems fairly apparent that the ape is man's immediate ancestor in the evolutionary series; but, whether he is or is not, a study of the ape brain will help us to an understanding of the brain of man. The brain of the chimpanzee closely resembles the brain of man, both macroscopically and microscopically. There is, in fact, a startling similarity between the two. For instance, in each there are the centres of the special senses occupying the same relative positions in the brain cortex; there are the same motor areas; and that area having to do with intellectuality in man has a silent counterpart in the chimpanzee brain. The arrangement of the convolutions is the same in both brains, except that, in the brain of man, they are more numerous and more complicated. In the chimpanzee the brain mass is smaller, weighing not more than six hundred grammes, while the brain of man may weigh as high as eighteen hundred grammes. One can understand that the brain of six hundred grammes cannot be the brain of eighteen hundred grammes; it may resemble it, but it cannot approach it functionally. Being so much smaller, the area of each centre will be smaller, and the centres, lacking in development, will not have the vigor that the centres of the larger and better developed brain will have. The smaller the brain the less its influence, and the less manlike its possessor. We are not surprised at the lack of intellectuality in the chimpanzee. We know that he belongs to the lower animals, and, consequently, we do not expect him to possess any of the special attributes of man. Nor does he give any evidence of possessing them. He is merely an animal, with the animal's five senses at his command, but beyond that he does not go. He is a primitive animal, and the primitive animal had nothing to concern him except that which came to him through these channels. The round of his daily life was limited by his activities: his experiences came to him through his activities, he was not able to sit down and to imagine things. He had action, but it was action that did not need the assistance of thought; it was brute action, not man action.

And here an interesting, if not significant, fact becomes apparent. If the thought area is present in the chimpanzee brain, why is there no thought there? Why is this area inactive? Why should it be there at all if it is not active? Why should there be any structure in the animal organism that is not in active function? There can be only two reasons for this: either the inactive part is a vestige of something once used by the organism and now disap-
pearing through disuse; or, it is something in the process of development, something that is to be of future use to the organism. Is this inactive portion of the chimpanzee brain a vestige of a once active tissue? Is it probable that tissue as important to the individual as this is would ever descend to inactivity? How could it? How could the organism do without this tissue once its importance had been established? Would it not be more reasonable to suppose that the reverse was the case? Might we not infer, with more probability of being right, that this portion of the chimpanzee brain is in the developmental stage? Might it not be developing after the manner of the man brain? and might it not, in fact, give us a hint as to the development of the prehistoric man brain? It may, too, offer some suggestion as to the further development of the chimpanzee brain. Might it be possible to develop the chimpanzee into a reasoning animal? The brain cortex is there, in lesser degree, to be sure, but it is there. All that is needed is a higher development, cultivation, and, given the proper conditions, why could not this be brought about? But its accomplishment would require a long, long period of time, so long a period that many, many generations would have to pass before any result would be obtained.

We do not know how long the brute animal existed before the man animal came upon the scene. nor can we determine just when, or how, the man animal began; but there does seem to be some evidence accumulating to show that the two are inseparably connected, and that the one is the outcome of the other. From time to time human bones have been exhumed from prehistoric layers of the earth's crust that tell us something of prehistoric man's physical condition. Through these we can trace man back through periods of descending skull capacity. His brain, according to this evidence, grows smaller and smaller as we get closer to the ape. until, at last, we get to where its weight lies at nine hundred grammes, or less. Recalling that the weight of the chimpanzee brain is in the neighborhood of six hundred grammes, we perceive that the two are really very close together; so close, in fact, that the interval might easily be bridged by the evolutionary process.

If we possessed the brain of a primitive ape and one of a primitive man, and could compare the two, and these again with the brain of modern man, we would have no difficulty in perceiving the differences in the three. We have not the primitive specimens, of course, but we can supply the deficiency, after a fashion. For an example of the primitive ape brain we can go to the chimpanzee of to-day. This brain is, probably, about the same as that of the primitive chimpanzee. With the aid of the chimpanzee brain and imagination we may obtain some idea of the brain of prehistoric man. In order that the appearances of, and the variations in, these brains may be the more apparent, I have had paintings made to show the characteristics of each. Each picture, reproduced here as a photograph, shows only the lateral aspect of a portion of the brain, the cerebrum, which is enough for our purpose. The dark areas in each indicate the area of what I call the primitive centres; that is, the first centres of the animal brain, those of the special senses, and those of the motor area. These, having existed from the very beginning of the animal brain, certainly may be named primitive.

Figure 1 shows the left side of the cerebrum of the chimpanzee, this picture having been made from the brain of a once living, adult chimpanzee of to-day. It will be seen that the cerebrum is small, and that the area of the primitive centres occupies about one third of the lateral surface. The balance of the surface here shown corresponds to that of the higher centre area in the brain of man.

Figure 2 shows the cerebrum of prehistoric man, as it might have been. Imagination has of necessity been drawn upon in the making of this, but I do not believe that imagination has led us so very far astray. Here the brain mass has increased, as has, also, the area of the primitive centres; but the area of the primitive centres seems to have in-
increased in a proportionately greater ratio than the area of the higher centres.

Figure 3 represents the cerebrum of man as it is to-day. Here the brain mass has attained its maximum weight, and the relative proportion between the area of the primitive centres and that of the higher centres has returned to that in the chimpanzee brain. This brain is nearly three times the weight of the first, and, while the proportion between the areas is the same in each, the areas of the man brain are much more extensive than those of the chimpanzee brain; that is, they occupy more cortex.

These pictures seem to suggest a regular sequence in the development of the animal brain. The chimpanzee brain is merely a primitive brain; there are no active areas beyond the primitive centres. The brain of prehistoric man is larger, and the higher centres are coming into function; as the brute began to ascend in the scale his primitive centres developed the adjacent cortex. And then, as the new function grew stronger and stronger, additional portions of the cortex were developed; thought and reason came into existence, and the brain of modern man was the result.

We now can understand how the brain began, especially that part of it relating to man; we see how it has been built up through the demands of the organism, and from this we may determine how the brain cortex may be further developed. We have, in short, reached to the very foundation of the brain itself; and this brain foundation is nothing more than education foundation; the one is developed through the other. If we wish to develop the brain of an individual we must begin at the beginning of that brain, just as the evolutionary brain began. Now, the individual brain begins before the individual is born, but does not become a working instrument until some time after birth. For a number of years it is in the developmental stage, just as the evolutionary brain was for so long; only the brain of to-day accomplishes within a very few years that which required uncounted centuries in the other. But, as in the older, so in the new: the same process must be gone through with, the development must follow the same method. The child brain cannot develop except as the evolutionary brain developed. And so, in the teaching of children, the teaching must be along developmental lines, for teaching is nothing more than brain development; and unless we know how the brain has come to us, our teaching will be a failure. The points to be remembered in this connection are these: That the primitive brain was a brain of action; that, in the development of new cortex, the new centres came through the primitive centres; and that the child brain, having the physical characteristics of the brain of primitive man, is, for the time being, a primitive brain. We must, in short, remember that the higher centres were developed through the primitive.

In the beginning the brain was developed because the organism needed it; this collection of organs of different function required a harmonizing agent, and the brain was the result. Its growth began through action, and so continued. The brute brain was developed through the activities of the animal. As the animal got higher and higher in the scale his activities became more and more complicated, more and more manlike, and his brain area increased accordingly. This increase began in the primitive centres and, then, as the demand became greater and greater, new areas began to push out from the old. The new demand arose through the accumulation of experiences, and was for a place to store and to classify them. And it was through this that thought and reason began. Thought is only the recalling of the experiences of the individual in logical sequence, and reason would be but a farther step in the process, the weighing of these experiences one against another. Before thought could begin, experience was necessary; and the brain needed to accumulate its store of experience through long, long epochs before that experience became available as thought material. But, after this accumulation had reached a certain stage, the impulse to push out was irresistible, and the further development of the cerebral cortex began.

The daily life of primitive man, like that of the primitive ape, was a life of action, just a certain round that varied little from day to day. Man was then but little better than the ape, but his progress had begun. Thought was coming, but its development was slow, for, although his life was an active one, the action almost always was along the same lines; there was little to vary the thought impulse. It was only an unusual occurrence that would break the monotony and give to the brain a new sense impression, but these unusual occurrences did not come often. They were very rare at first and, as more than one impulse was needed to make the brain impression permanent, to create new cortex, the process was, of very necessity, a long one. For illustration, let us trace the origin of the spear, one of the primitive weapons. No doubt the club was the first weapon used by man. Now, suppose, in a battle with another, some one of the first primitive men, in using his club, split it, leaving in his hand a fragment with a sharp end. In the frenzy of combat this was unnoticed until, thrusting it fiercely about, he pierced the body of his adversary, killing him. What would happen then in the mind of the first man? His curiosity would be aroused, and, wondering, he would approach his victim and look at the wound. Then he would glance at the stick in his hand, and the shadow of a thought would fit across his mind. The association of the facts of the wound and of death, the idea of which already was in his mind through previous experience, with the fact of the new weapon in his hand, an alteration of the club idea already in his mind, aroused a vague impulse within his brain in which the old ideas and the new were mingled. And then he thrust his hand against the end of the stick and felt its sharpness. At that instant the spear idea crystallized. An entirely new idea would demand a new spot in the cortex, but a new idea growing out of an old would find a place partially prepared for it. In this case because the spear idea was an offshoot of the club idea, it would secure a lodgement within the area of the club idea. This lodgement would be insecure because of the element of newness therein, and because, also, only the one impulse had been received. But the first impulse would mark the path, and other impulses following later, would fix the path as
a permanent way. In this manner would new areas be brought into development, but this development would be, not the event of one day, but the events of a hundred days, perhaps of a thousand days. The brain cortex does not develop instantaneously. It is a slow process at its best; and how slow it must have been in the brain of primitive man! But the task was accomplished, and the brain of action brought forth the brain of thought. The brute brain was a brain of action, the brain of primitive man was a brain of action, and the brain of modern man, while not entirely a brain of action, still is dominated by the primitive centres. These centres lead, have control, and, if we wish to understand the brain of modern man, or to attempt anything with it, we must approach it from that direction. Another important fact becomes visible here. That is, that the modern brain is an organ of comparative youth. It is, actually, from the point of view of evolution, the youngest of man’s organs. It has been the last organ to develop, for it has been the last for which the organism felt the need; and, beginning as a mere controller of animal activity, it has developed into an organ that not only controls animal activity, but one, also, that controls the destiny of its possessor.

Teaching has to do, mainly, with the child brain, and the child brain is, essentially, a primitive brain. Action is the main spring of each. In the child, activity brings experience, and his experiences are stored within his brain centres for future use, for the development of thought. It must follow, then, that the child’s thought will be of no greater value than the value of his experiences. It is surmised that the human brain at birth possesses all the cortical cells it ever will possess, that no mere will be developed during the life of the individual; but these cells, in the child, are not yet all in full development. As the child grows, the brain grows, and, as the organism needs them, the cells comprising the various centres come into function. Repeated sensory impulses cause the cells to increase in size and to become active. The brain centres come into activity in the following order, smell, taste, sight, hearing, tactile sensation, and thought. That is to say, the centres of the special senses become active first, then the motor centres, and then the higher centres. Of the white fibres constituting the central portion of the brain mass there are three kinds: The afferent, which carry impulses to the cortical centres: the efferent, which carry impulses from the centres; and the association fibres, which cross from one centre to another. Of these, the afferent, transmitting sensory impulses, develop first; the efferent, transmitting motor impulses, second; and the association fibres last. In the special sense centres the afferent fibres predominate, as the impulses here are mostly sensory; these centres having little or no use for motor impulses. In the motor area the two sets of fibres are about evenly divided, for here each sensory impulse demands an answer.

It is through this sequence of development that we begin to understand how to approach the brain. The sensory fibres, being the first in commission, are the first to transmit impulses, and these impulses are received through a period of time before the motor fibres are ready to respond; and still later comes the interchange of impulses between the centres. No centre is ready for real function until the sensory impulses have established themselves and the centre has been taught its function. No centre is ready for full function at once. It needs experience; that is, development through activity, before it can give its full service. It is this experience that teaches it, that arouses its latent function; and it is only through experience that the full power of the centre can be brought out. And then, when the centres are all in full function, the association fibres make possible the interchange of impulses, of ideas, between the centres. The human brain does not attain its full weight until about the eighth year of its existence, and therefore it cannot be of full value to the individual before then. Up to that time there is only, as it were, half a brain in function, for, up to that time the dominant part of the brain, just as in the primitive brain, is the primitive area. Real thought does not exist for such a brain, for thought cannot exist until the thought mechanism can act; and the thought mechanism will not act until the centres have stored up enough experience to give them a basis upon which to act.

The foundation of education, then, must be laid through the primitive centres; there is no other way by which we may approach the higher centres, no other way properly to develop thought. After the centres have developed, after there are enough stored up experiences, thought comes. After that the individual can think without the aid of action, but action is ever an aid to thought; for that which has become a habit, a fixed method, in the brain cells never loses its control there. So we see how important this matter of the foundation is. The mere laying of it establishes a habit. That is, the manner in which a fact is acquired determines the manner of its use later; it also determines the manner of acquisition of other facts. If we wish to learn something we must learn it in the same manner in which we are later to use it. In teaching a boy to drive a nail we do not hand him a nail and a hammer and tell him to go ahead. That would be aimless, and would lead to a waste of time, and to the acquisition of a faulty method. The human animal must be trained in order to make him effective; each human brain must be trained in the right way if we want the best from that brain. And so, when we give the nails to the boy, we begin by showing him how to drive them, and we strive to make the process interesting. Not only do we give the hammer and the nails to him, but we give to him, also, something into which he can drive the nails, some boards. We show him how to put the boards and the nails together; that is, how to make something. In learning how to adjust the boards, as well as how to drive the nails, he learns several facts at the same time, facts that attract his attention, that become interesting through association, and facts that, later are going to be of service to him. If he ever should want to make something with boards he will know how to begin; the basic idea is firmly fixed within his brain through association. It does not matter if the work to be done differs somewhat from the work which he learned how to do. He will accomplish it, for the foundation for right procedure was laid in the first instance. Once an idea is set in the brain
centres, once a pathway is established, it is difficult for the brain to ignore it. The brain is peculiar in this, it holds to what it has. It is, therefore, of the greatest importance that which is learned is learned in the proper manner. If learned in an improper manner the improper way always will be in evidence; the wrong pathway, the wrong impression, once having been formed, will remain within the brain, even though the right way be learned later. It is impossible for brain cells to unlearn, to give up an impression. It must follow, then, that, to make the brain of the highest efficiency, we must teach it early, before there is time for it to learn the wrong ways.

This manner of learning should begin early, but teaching, formal teaching, should not. The brain is not ready for real thought before its eighth year, and so, anything requiring thought should be barred until then. Before that we have the primitive brain to consider, and the primitive brain itself considers only action. There should be no formal schooling for a child under seven years of age, but the foundation of its education should be begun. That is, we should lay down the right pathways, not forgetting that these pathways come through action. The child under that age should have an active life, but it should be action that is under proper direction. He should not be thrust out into the back yard or upon the street to pick up things for himself, mostly undesirable things; his activities should be so directed that he will learn useful things through them. The little child comes into knowledge of the external world through intimate association with it, through contact. That which he learns he learns unconsciously, without effort, and as a matter of fact through constant and every day association with it. He learns to say “Mama” through hearing the word many times, day after day. The impulse reaches his brain through the afferent nerve fibres, and, after a sufficient number of these impulses have been received, the motor centres controlling the muscles having to do with speech awake to the consciousness of the word, and, acting upon that consciousness, the muscles coordinate and pronounce the word. But, even after the word is pronounced, the centres are not in immediate control of it; their control is not perfect at the first attempt, nor yet at the second. The word impulse is so complicated that it requires many repetitions before it is learned. This illustrates what we said in regard to repeated sensory impulses being needed before a centre can come into active function. It is the repeated hammering that drives the nail, not the first blow, although the first blow must be a careful one, as that determines the direction in which the nail is to go.

And this should be the manner of the acquisition of knowledge by the very young; in that manner should the foundation of an education be laid. Children under eight years of age should learn, but learning should not be forced upon them. The process must be made interesting and understandable from their point of view. Most children, at any age, learn with difficulty under the ordinary school routine, and, usually, have to be driven to their books. That is because, first, they do not begin in the right way, and, second, because the work is not presented so that they may grasp it. If these children learn anything at all, it is only through sheer memorizing of facts. But it is not the memorizing of bare facts, facts that only are to be repeated parrot-like, that constitutes education. Education is the individual, and, more than the individual; it is the present and the future, the individual and the world. It is the welfare of both that is determined by the foundation of the individual’s education, by the development of the child’s growing brain.

AN ANALYSIS OF FIVE HUNDRED FATAL MEDICAL CASES IN THE TROPICS.

With the Clinical Diagnosis in the Light of Autopsy Findings.5

In all hospitals there will be found a group of cases similar to those in this list, which constitute a veritable apple of discord between clinician and pathologist. Cases one to four are examples of fatalities which the clinician believes ought to be classed as malarial or postmalarial deaths. In all these cases the clinician’s laboratory had found the estivoautumnal asexual malaria plasmodia in the peripheral blood on the day of admission. In case two they were present in such large numbers as to be marked plus. The parasites were again found in this case on the day of the death (fourth day) in much smaller number. In the fourth case they were found on the first, second, and third days. In case one the patient died on the tenth day, having...
run a more or less remittent, high fever. Ante and post mortem cultures of the blood remained sterile. The leucocyte count was 9,800, with a differential of fifty-six polymorphonuclears, five large and thirty-nine small. The secondary diagnosis of tuberculosis was more of a guess than a clinical deduction, and was followed, as so often the case under like circumstances, by a flat failure. Case two shows two distinct paroxysms of fever on the second and fourth days. In the latter one of these the patient succumbed. To the clinician this death presents a strong case for argument in defence of his definite diagnosis, especially since a large number of parasites were found on the day of admission and a smaller number on the day of death. At autopsy very slight microscopic malarial pigmentation of the spleen was found. No mention is made of parasites. In case three the patient was admitted in coma, and remained so until death, on the third day. Case four shows the typical temperature curve of remittent malarial fever, with recovery on the fifth day. On the seventh day a quinine urtica was so severe that the remedy was discontinued. The temperature remained normal for twelve days, during which the patient was up and eating full diet. On the thirteenth day the temperature suddenly rose to 105.5° F., and the patient died. The chief findings at the autopsy were focal necrosis, extensive albuminous degeneration, and multiple minute abscesses of the liver. Cloudy swelling of heart and kidneys was also found.

Much discussion has been aroused among the staff of this hospital as to the cause of death in these and occasional similar cases. A number of different opinions are held, the chief of which are: 1. These deaths are due to quinine poisoning, causing necrosis of the liver and cloudy swelling of other organs. 2. They are acute infections of unknown origin, independent of malarial infection. 3. They are malarial or postmalarial sequelae, the result of poisoning by malarial toxines, in cases where the instituted quinine treatment has destroyed most parasites, and thereby liberated large quantities of toxine. The supporters of this theory also assert that the malarial parasites and pigment found at autopsy in many of these cases are often the visible remainder of the recent infection, and not the usual chronic malarial infection of the tropics. The cloudy swelling and the necrosis, especially of the liver, are easily explained by assuming that the malarial toxine has been the causative agent. The factor seemingly against the first argument is that these patients do not receive more quinine than the average severe malaria patient who recovers. Furthermore, when quinine does cause poisoning, beyond the unimportant tinnitus aurium and deafness, it manifests itself as a temporary ameblophia with widely dilated, nonreacting pupils.

This symptom, always carefully watched for when quinine is given in heavy doses, i.e., sixty grains in twenty-four hours, to eighty grains in eight hours, has never been observed in any of these undetermined deaths following malaria under treatment. The second argument lacks essential support because of the inability, so far, to obtain any but sterile cultures in ante or post mortem blood, and from post mortem tissues. In the presence of a decided malarial infection on admission, and in the absence of other findings at autopsy, the clinician feels that the assumption of malaria having been the direct or indirect cause of death should be sustained.

Case five may have been a posthemoglobinuric fever death, in which the only evidence remaining at death was an acute degenerative nephritis. The secondary diagnosis of lobar pneumonia was a mistake caused by extensive edema of the lungs shortly before death. Case six represents a death similar to those in cases one and four, but it was a case in which neither clinician nor pathologist had attempted malarial diagnosis. Malarial pigmentation of the spleen, liver, and bone marrow was found at autopsy, with necrosis of the liver and multiple abscesses of the lungs. The patient was an infant boy twenty months of age. The blood examination was negative on admission, but quinine sulphate was given, one dose of ten grains on the second day, three doses of five grains each on the third and fourth days. Death occurred on the fifth day. Possible evidence of syphilis was found in the femurs at autopsy. Case seven was an adult negress who was admitted to the hospital suffering with tertian malaria and a pustular dermatitis. The blood was positive for tertian parasites, and the Wassermann test was negative. Death occurred after seven weeks of practically afebrile temperature, from exhaustion. Put from an arm pulse remained sterile when cultured. A culture from an open leg ulcer was positive for Micrococcus aureus. At the autopsy an ulcerative condition of the mouth and colon was found, in addition to the dermal infection. In case eight, bacteriological examinations of the blood, spinal fluid, and blood serum (Widal and Wassermann tests) were all negative. The patient died in three weeks with symptoms of acute meningitis. The conditions noted, coupled with a persistently low leucocyte count, caused the diagnosis of tuberculous meningitis to be made by exclusion. At the autopsy, the post mortem changes were found far advanced. Atrophy of the frontal convolutions of the brain and an excess of the cerebrospinal fluid were the only noteworthy changes. Tuberculosis was not present.

The following five cases (nine to thirteen) were classed as ill defined by the pathologist. Case nine was admitted in coma, temperature of 103° F., pulse 126, respiration 26. The leucocyte count was 20,000. Malaria plasmodia were not present. Signs of meningitis were the only physical findings. The spinal fluid was negative when cultured. Death came in thirty-six hours. Autopsy showed acute follicular colitis (focal), dry mëninges, and sinuses, with congestion of the pia mater. Cloudy swelling of the heart, liver, and kidneys was also recorded. Case ten presented estivo-autumnal malaria parasites in the blood, on admission. A lobar pneumonia, with a leucocyte count of 38,000, was also found. The temperature was low intermittent until death occurred, on the fifteenth day. At the autopsy such a multitude of complications, such as acute degenerative nephritis, and acute purulent cystitis, were found in addition to the lobar pneumonia diagnosed clinically, that
the case was placed in the ill defined category. Case eleven is an especially interesting one. Clinically, a diagnosis of cerebral syphilis had been made. The patient was a Barbadian negro, thirty years of age. He seemed mentally dull, presented glandular enlargement, genital scars, acute periorchitis of the sternum and tibia, mucous patches, and evidences of a fading skin eruption. His temperature was 103° F. on the day of admission, but fell to normal on the second day. The fever curve fluctuated between normal and 100° F. for the next eleven days. On the eleventh day he was given 0.5 gramme of salvarsan intravenously at 11:20 a.m. At 4:00 p.m. that day his temperature had risen to 104.5° F., his pulse had jumped from 88 to 135, and he died at 7:40 that evening. This patient had been up and about, eating full diet, the ten days preceding the salvarsan treatment. Due probably to advanced post mortem changes, definite pathological findings could not be obtained. Acute degenerative encephalitis, right basal ganglia, seemed to be present, but was held by the pathologist to be, possibly, a post mortem change. Other findings were of no importance. This case, by the chart records, strongly calls to mind similar fatalities reported, following salvarsan treatment, in cases of advanced or cerebrospinal syphilis. Case twelve presented all the clinical signs of acute meningitis. The spinal fluid was negative when cultured. Edema of the brain and congestion of the cerebrospinal meninges, in conjunction with cloudy swelling of the principal viscera, were the chief results of autopsy.

Case thirteen is similar to the malaria cases cited at the beginning of this group, with the exception that ulcerative enterocolitis was also found at autopsy. The patient lived seven days after the discovery of malaria parasites in the blood. The temperature became progressively higher, in spite of energetic quinine treatment. Death occurred with a terminal rise of 106° F. Ante and post mortem blood cultures remained sterile. The last four cases of this group (fourteen to seventeen) represent not so much a difference in the findings of the clinician and the pathologist, as a difference of opinion as to what lesion to hold responsible for the patient’s death. Case fourteen was a chronic ulcerative enterocolitis, in which megaloblastic degeneration of the rib marrow with hyperplasia of the femur marrow led the pathologist to assume that the severe anemia recognized clinically was of primary importance. In case fifteen the patient died on the seventh day following admission, with a temperature of 109° F. Clinically, the case was considered to be a septicaemia of unknown etiology, with a terminal bronchopneumonia. At autopsy an acute hemorrhagic fibrinous pleuritis was found, in addition to bronchopneumonia. The former was so severe that the pathologist accepted it as the cause of death. Case sixteen was considered pellagra by the clinician and syphilis by the pathologist. Whether the death was caused by either the former or the latter, or both, is quite impossible to decide by the remaining records. Possibly, in the absence of blood cultures, these two terms should be accepted as synonymous in this instance. The seventeenth case represents a final difference of opinion occasionally held by clinician and pathologist. The clinician diagnosed chronic nephritis complicated by a hypertrophied and dilating heart. The latter complication was especially evidenced by the presence of a large, smooth, and tender liver, assumed to be the result of passive congestion. The pathologist, at the autopsy, verified the clinician’s renal and cardiac diagnosis, but found, in addition to hepatic congestion, an acute necrosis with fatty degeneration and red atrophy of this organ. The pathological changes of the liver were then taken to be of paramount importance, with the cardiac and renal findings as coincidental or secondary, while the clinician had shown his opinion to be exactly the reverse. How shall we decide who is right?

**Group VIII. Neoplasms (38.46 per cent. failures).**

</tr>
</tbody>
</table>

The neoplasms of this group were all in negro patients. Cases one, two, and three were looked upon as tuberculous bone caries producing transverse compression myelitis and meningitis. Case four was mistakenly diagnosed gumma, though the Wassermann test was negative. Case five is an excusable error, though a history of four months’ headache and a continuation of symptoms for four weeks longer under observation in the ward, the first two of which had a recorded afebrile temperature curve, might have suggested tumor, rather than abscess, of the brain.

In the main, the errors of this group seem very excusable. The outlook of these patients was, of course, quite hopeless from the beginning, irrespective of diagnosis.

**Group IX. Hepatic (54.54 per cent. failures).**

In the life of a physician in the tropics the first four cases of this group represent an affection that is the bane of the diagnostician. Case one shows an excusable error. The patient came in the medical wards with a liver abscess that had ruptured into the peritoneal cavity, before admission. The abdomen was distended with fluid (of which a gallon was withdrawn), resembling the exudate of tuberculous peritonitis. Nevertheless, the etiology being doubtful, he was sent to the surgical division for exploratory laparotomy. This revealed the true state of affairs. Cases two, three, and four were not diagnosed, because, in the first place, sufficient fresh stool examinations were not made to determine the nature of the existing dysentery, and, secondly, because repeated routine physical examinations had been carelessly omitted. Case five
Group X. Pancreatic (100 per cent. failures).

<tr>
<td>Chronic pancreatitis</td>
<td></td>
<td>Clinical myocarditis and nephritis</td>
</tr>
</tbody>
</table>

Though chronic myocarditis and chronic nephritis were present in this case, a chronic pancreatitis, presumably of syphilitic origin, was the chief lesion found at the autopsy. No apologies nor explanations need to be offered for this error of omission. The case simply shows how rare, and how inaccessible to diagnosis, diseases of the pancreas are.

Though all efforts have been made to condense this paper as much as possible, we find the time and space allotted us too limited to take up the many interesting and instructive errors of omission and commission that were made incidental to determining the actual cause of death. As many of these errors would also be found to be repetitious of what has already been said, we shall content ourselves by drawing conclusions from the matter in hand, disregarding all errors made in secondary and incidental diagnoses.

Conclusions.

Without autopsy findings, our opinion as to the cause of death is correct in only somewhat over 80 per cent. (81.40 per cent.) of our fatal cases.

With autopsy findings, a satisfactory cause of death can be definitely established in somewhat over 90 per cent. (90.66 per cent.) of all fatal cases.

The great majority of our mistakes to diagnose clinically is due to neglect of some elementary, routine examination, either physical or laboratory.

Fortunately, in the above presented series of 500 cases, had there been no errors in diagnosis, and appropriate treatment adopted in every instance, the chances of recovery would have improved in only 2.4 per cent, of the total number.

If the pathologist would take into consideration more frequently the clinical, as well as the post mortem findings, in determining the causes of death, the number of undetermined infections and ill defined diseases would be materially reduced, and in some questionable cases definite conclusions could be reached.

Cutis—Index Morbi.

By William P. Cunningham, M.D., New York, Clinical Lecturer on Dermatology at Fordham University; Assistant Physician, Harlem Hospital, Dermatological Department; Clinical Assistant, New York Skin and Cancer Hospital.

Some wag has said that dermatology is the science of vanity: that a woman will endure with stoicism a crippling pain in the back, but will move heaven and earth to get a pimple off her face. Like most alleged witicisms at the expense of the serious things of life, this fling contains but a fraction of the truth. Presentability is not the only function of the skin. It is a great organ of protection and excretion. It guards us against the invasion of destructive bacteria, adapts our organisms to thermal fluctuations; by its delicate nervous mechanism warns the brain of dangerous contacts, and enables it to execute many marvels of artistic cunning. It can impart a feeling of perfect satisfaction or harry with the most exquisite torture. It supplements the kidneys in the mighty labor of elimination. It is only to the shallow mind, therefore, that the study of the skin would appear to be trivial and vain. It must be a subconscious approval of this contemptuous attitude, that so meanly subordinates the dermatological department in the minds of medical students and in the curricula of most medical schools. It is considered a waste of time to devote any of it to dermatology, when there are so many graver subjects for study. Who would concern himself with acne as compared with acromegaly? Contrast the relative importance of psoriasis and pneumonia! How pitiful is pityriasis paralleled with cholelithiasis! Think of tinea and tabs! think of eczema and rabies! Out upon pediculosis; note this cardiac stenosis! Et similia multa exempla! What adult mind but would advert at once to the more serious business in hand and sweep aside, as beneath its notice, the contrasting cutaneous lesions?

Yet a little experience will reveal, as a little reflection might have done, that ignorance of skin diseases is a material drawback to the general practitioner. Skin diseases are very common. They are a great annoyance to the patient, either through their unsightliness, or the positive physical distress that they produce. Acne may not possess the morbid possibilities of neurasthenia, yet I have seen it more than once bring about the latter condition because of the constant brooding it entailed. It has prevented marriages and lucrative employment. Its victims have been stung into suicidal fury by the caustic comments of inconsiderate associates. They become shy, retiring, morbid, and unhappy. Are not these adequate reasons for considering acne worthy of the attention of our august neopractioners? Because it does not kill it is nonsense to ignore it. It may destroy a lovble disposition, warp an ardent spirit, and crush commendable ambition. And if after these considerations, the Esculapian debutant is still unimpressed, he will speedily ascertain, in the friction of medical practice, the importance of the patient point of view, by the loss of remunerative occupation.

The itching dermatoses are often responsible...
directly for deterioration of health through constant irritation of the nervous system. "Itch hath murdered sleep" just as effectually as Macbeth is reputed to have done. Dermatitis herpetiformis, insistent, insatiable, and intractable, is as serious a disease as many of those absorbing the physician's attention, yet how few physicians, apart from those making a special study of cutaneous disorders, are able to diagnose it correctly! It runs the gamut of all the "eczemas" till the sufferer is worn out with torment, and the hope deferred that maketh the heart sick. Finally, when the dermatologist gets him, he has to begin operations on a patient lacking faith, hope, and vitality. Hard as may have been the original problem, it is rendered almost insoluble by the deplorable morale following repeated failures.

In addition to the dermatoses operating evilly on the mind, and those producing the exquisite agony of pruritus, there are others that are directly dangerous to life. Carcinoma cutis, sarcoma cutis, epithelioma, gangrene, malum perforans pedis, malignant pustule, guana, and lupus, are illustrations of cutaneous diseases, sufficiently destructive to arouse the interest even of the gravest minds. If the physician has only an indifferent smattering of dermatology, he may be unable to differentiate these conditions from others somewhat resembling them, and the patient may lose his life, or a special sense, or be grossly and hideously disfigured in consequence. Variola, scarlet fever, and even measles are grave enough in their immediate and remote effects, both to the patient and the community, to lift dermatology into undeniable importance. When a case of syphilis so closely simulates variola that experienced men are of divided judgment, who will say that the time spent on dermatology is wasted? Suppose that variola were simulating syphilis, a blunder might scatter the seeds of contagion among the people. And suppose as has also occurred, that during an outbreak of variola, a case of measles is mistaken for it, what consternation overcomes the vicinage, and what lasting ridicule is cast upon the misguided practitioner! There is no indulgence on the part of the community, in consideration of the difficulties of the diagnosis. Blunders are unpardonable, and what blunder could be greater, in the minds of the laity, than the confounding of measles and variola? Yet the man who made that irretrievable faur pas was one of the brightest men of my acquaintance, with a profound contempt for dermatology. The work of years, in building up a practice, through a well-grounded knowledge of internal medicine, was seriously threatened by this single exhibition of ignorance.

As a practical factor in the everyday application of medical science, I think it is obvious, from the foregoing reflections, that dermatology deserves the profoundest consideration. But it was in relation to another aspect of the subject that this paper was designed. Cutis—Index Morbi. The skin the index of disease—the sheet on which is shown the whither of our quest. This has not to do alone, or mainly, with diseases of the skin. It has to do with the indications on the skin of internal disorders. The diagnostician, with an eye for all that is to be seen, can often get valuable information, for the direction of his efforts, from a preliminary survey of the skin. A trite demonstration of this is familiar to all in the jaundice accompanying disease of the liver. Bronzing of the skin leads us straight to the suprarenal capsules. We have all noted the earthy hue of carcinoma. The pallor of anemia is a matter of common observation: as a variety thereof, recall the greenish-yellow tinge of chlorosis. The red flush of fever is promptly appreciated even by the laity. Purplish ecchymoses are often the telltale sign of fracture. The same color disseminated in spots of various sizes over the lower limbs leads to the diagnosis of rheumatism; so do the shiny red painful infiltrations of erythema nodosum. The violaceous nose of chronic alcoholism hardly calls for comment. In passing it may be well to remember the preliminary stage of acne rosacea, and the terminal stage of rhinophyma. The golden deposits of xanthoma often betray an unsuspected diabetes. The brownish splotches of chloasma hint of diseased uterus or ovary. Melanotic navi give warning of the sarcomatous predisposition. An exaggerated flush on one cheek with dyspnea shows which lung is involved in the pneumonia. Rose-colored spots on the abdomen of a fever patient may clear up an obscure case even before a Widal is available. Erythema. roseola, or petechiae, may settle a dubious diagnosis of cerebrospinal meningitis. The muddy look accompanying intestinal torpor is everywhere in evidence. No one will mistake the puffy, pasty skin of chronic parenchymatous nephritis, or the blue of cardiac insufficiency. Contrast the dry anhidrotic skin of chronic interstitial nephritis with the tense and waxy myxedema of the atrophied thyroid.

Herpes labialis was formerly regarded as a sign of malarial infection, and I have proved it to my satisfaction many times. Herpetic lesions in association with a belt sensation or lightening pains point to tabes. Of like significance are decoloration of the hair (gray or white in patches), falling of the nails, local perspirations, sudamina, ecchymoses, and bullae. Note also the local variations of temperature, caused by diseases of the central nervous system.

Irritative lesions of the nervous system are frequently indicated by the so-called glossy skin, which is atrophied, thin and shiny, and tightly stretched over the subjacent tissues. Persistently recurring boils and genital pruritus, like xanthoma, may be diabetic. Mark the cutis anserina, algid skin of child. Mark its occurrence also in acute intestinal disturbance. Angioneurotic edema, erythema multiforme and urticaria, variants of the one pathological entity, products of a common cause, hark back to the auto intoxication of intestinal pureraction.

Chronic congestion of the face, neck, and ears, in connection with mental dullness, and feeble circulation, arouse a suspicion of chloral addiction. Persistent pruritus, general, local, or both, traceable to no eruption, and accompanied by nictitation, and contracted pupils, furnishes a pretty accurate picture of morphine habituation. Multiple small abscesses, within reach of the patient's hand, indicate positively the manner of its administration.

Tophaceous deposits in the helix of the ear lead unerringly to the diagnosis of gout. Friability of
the nails should suggest a search for other evidences of lithemia. Lithemia is a term treated with icy scorn by the pathologists of to-day, as conveying no scientific conception of the morbid condition to which it was applied. But in the minds of its framers it clearly meant that state of overnutrition leading to the precipitation of excrementitious matters and the formation of calculi. It seems to me, even in the light of our present knowledge, that it is a very serviceable and expressive term.

How important it is to recognize the digit mortui, the cadaveric, icy, shrunk fingers of Raynaud's disease! Even if you cannot cure the patient, after you have recognized his malady, you can perform the very material service of "saving your face" with the family, and establish a reputation for astuteness.

Be not deceived by the dermatitis factitia of hysteria. Strangely appearing lesions that fit into no recognized pathological picture should always excite suspicion. If a woman presents herself with linear, angular, crisscross, or other bizarre configurations, confined to regions within access of her hands, search diligently for the stigmata of hysteria. Malingerer for sympathy, for profit, or for deviltry, is not at all uncommon among women and even among men.

The clubbed fingers of tuberculosis point grimly to the lungs. Erythema induratum, lupus vulgaris, and scrofuloderma warn us of the tuberculous diagosis. The various tuberculides indicate that the toxins of tuberculosis are active in the patient, and that graver manifestations may be apprehended. A knowledge of the multiform eruptions of syphilis, and of their differentiation from other dermatoses, constitutes in itself a liberal education in cutaneous disorders. For he who can boast of as broad a grasp as that which has learned to recognize the legion of diseases with which the great imitator may be confounded. Needless to emphasize the gravity of overlooking syphilis.

The early recognition of lepra is urgently demanded, in the interest of the patient and the community. While not actively contagious, it has been demonstrated that it is communicable after prolonged exposure. And whatever is to be done for the patient had better be done early if he is to receive any benefit at all. This early recognition can only come through acquaintance with its manifestations of invading the skin. Fresh in my recollection is the embarrassment of a good diagnostician who overlooked scarlet fever in an adult male:

The patient had the typical throat of tonsillitis. Opinion was pronounced in accordance with appearances. The usual remedies seemed to be effective in rather a tardy manner. After a week he was allowed to go about as before. In a day or two more he turned up at the doctor's office with the announcement that he had some kind of a scaling skin disease. Examination revealed a general desquamation, distinctly scarlatinial. Here was a pretty mess! The patient lived in a large boarding house and worked in an office full of clerks married and single. The opportunities for the spread of the disease were ideal. The dilemma of the doctor was pitiful. If he confessed his error he was disgraced, if he concealed it he would be endangering the health of the community, and subjecting his patient to the possibility of a kidney complication. Finding no middle course he threw himself on the mercy of the patient, who fortunately was a man of sense and feeling, admitted his culpable carelessness, had him sent to a hospital for infectious diseases, patiently bore the abuse of the mistress of the boarding house who had to submit to the annoyance of disinfection, and took to heart the lesson that it is prudent to investigate the skin before pronouncing judgment.

One glance below the neck band and he would have read on the cuts—index morbi—writ large and unmistakable the diagnosis, scarlet fever.

A girl of sixteen years, of good family, and of a quiet and reserved disposition, never known to go about without her mother, was attacked with "a sore throat." A physician diagnosed tonsillitis. Treatment was not strikingly effective, and after a week another physician was called upon. He verified the first diagnosis, but could not understand the persistence of the trouble. After a few days of his medication, a third man fell heir to the puzzle. His suspicions, if aroused by the extraordinary prolongation of a simple pharyngitis, were lulled by the shy and modest demeanor of the girl, and the assurances of her mother, adroitly exerted, that she had absolutely no opportunity for mishbehavior; and he went completely off the track. When I saw her I found the sharply circumscribed redness of the palatal arch so suggestive of specific infection and insisting on the diagnosis of a tuberculous ulceration. Uncovering a belts of angulocellular eruption and the evidences of a preexisting chancr, faced with the facts the girl admitted her fault. Pressed by her mother for an explanation of when and where she had met the man, she said she had never been away from home, and had only for a few minutes, she said she had received him in her own home when her mother had gone out.

That eruption had been present all the time that she was under treatment by the other physicians, and had they consulted the cuts—index morbi—they would have read at once the correct diagnosis.

A woman of forty-four years had been bitten on the cheek by her husband in a spirit of playfulness. In about two weeks a hard papule appeared. She consulted her physician after two weeks more, and he treated it for trauma. When it resisted his applications and admitted of the submaxillary and the anterior chain of cervical glands demanded explanation, he expressed grave doubts of cancer. Much time was consumed in watching the progress of this possible cancer, and finally some two months after the appearance of the lesion I saw the case in consultation. The cheek presented an ulceration as big as a dime with indurated edges and a scanty discharge. The adenitis was spectacular. The patient's back and chest were dotted with large dark red fleshy papules of an unmistakable character. The patient was surprised that they had any bearing on the case as she thought they were hives!

They had been present a week, and had her physician searched her skin he would have awakened to her malady in a manner much more agreeable to himself. Of course, if he had had any suspicion of the true nature of the initial sore he could have had an examination made for the spirochete. But failing that, he would have come sooner, and by his own efforts, to a realization of the true state of affairs had he not ignored the cuts—index morbi.

A traveling salesman far from home discovers a "fever sore" on his lip. He consulted many physicians in the various towns through which he passed, and they all declared it was the same thing. After traveling nearly three months, he returned to New York, and sought the advice of his regular attendant in Brooklyn. Here again he was assured it was nothing. Irritated by the continual repetition of this stereotyped phrase and sensing a deeper significance in the sores of the disease various advices he made another venture and came to see me. I found a confirmatory roseola, and the chance was demonstrated beyond dispute.

The point is that the last two physicians who had seen him had had an opportunity to do the same thing: for the patient had observed "those
few faint spots" for about two weeks, but had not connected them with the initial lesion. They had not searched the index either.

Similar illustrations could be cited in great numbers. It will be conceded that something has been said in defense of the study of dermatology. Not only in combating diseases peculiar to itself is dermatology of grave and serious import, but in furnishing information whereby other systems may be intelligently guided. It should be advanced to a position of prominence in all our medical curricula, instead of being a side issue to which no well balanced medical student pays any attention.

How ill prepared is he to fight disease who cannot even read the cuts—index morbi!

VINCENT'S ANGINA.

BY LEO GREEN, A. B., D. M. D.,
New York.

The field of oral surgery has been rather thoroughly raked over recently in the medical and dental journals, and an article published lately, I am informed, treats in part of the subject I am going to take up. There will be no contention as to priority, as far as I am concerned. This is a narrative of my observations of noma for the past ten years or more and the successful treatment of Vincent's angina for nearly three years.

The mortality in noma, as stated by Doctor Holt (seventy-five per cent.), seemed impressive to me when I started to observe it, as a member of the attending staff of the Nursery and Child's Hospital, about ten years ago, and it appeared that he erred only in conservatism. Noma, or cancer oris, is a gangrenous stomatitis (it may occur elsewhere, as in the rectum) appearing generally in institution children or in those from poor surroundings, and found during the convalescent stages (or immediately thereafter) of measles, scarlet fever, whooping cough, and diphtheria, and in frequency, in the order named. During my early observations I did not see the little patients until the ravages of advanced noma were evident; little attention was given to the first oral symptoms, which were considered of no great moment. The usual surgical procedure of removal of soft tissue and dead bone, with frequent irrigations of potassium permanganate and sodium hyposulphite, and careful nursing and feeding, saved a few victims. But the progress was unsatisfactory, and, because of my uncertainty, I made no report of my infrequent success.

About six years ago, I began at the Foundling Hospital to observe all the patients suffering from the four diseases mentioned above and to carefully watch their convalescence. Somewhat later it occurred to me that Vincent's angina, observed in their mouths, was the starting point of cancerum oris; and if this could be arrested, the origin of the destructive disease was found. This theory has since been proved to be correct—cancerum oris is a neglected or aggravated Vincent's angina.

I tried, without success, irrigations of bichloride of mercury, permanganate of pothash, and other antiseptics, and then in turn discarded by process of elimination the various cauterants (including the several silver salts), until I hit upon trichloracetic acid, which I had previously used for other purposes. Trichloracetic acid belongs to a group of three acids (monochloracetic and dichloracetic are the other two), the difference in their composition being due to the relative amounts of chlorine they contain. It is made by the oxidation of hydrated chloral by nitric acid, and occurs in regular, colorless crystals. I started using a twenty per cent. aqueous solution, but have since found that acid in the full strength gives me the best results. The caustic is applied to a freshly cleansed dry surface to prevent its being floated about in the saliva; to avoid extensive cauterization, the tissues are painted with melted petrolatum or other grease, leaving only the infected area exposed. To lessen the pain of cauterization, I drop a few acid crystals into six or eight drops of a per cent. solution of novocain, and the results are satisfactory, judging by the absence of pain. In addition to the cauterization, which is repeated every two or three days as needed, the mouth is irrigated with 0.5 per cent. solution of formaldehyde, or, if the odor is very bad (there is a characteristic odor in all advanced cases), I alternate with irrigations of permanganate. As a matter of experiment, I omitted all irrigations in several cases, to observe whether the acid alone would destroy the disease—it does. Vincent's angina (oral) appears first as a gray ulcerative area at the gum, festoons of the incisor or molar teeth, or both, and on the inner side of the cheek, usually around the orifice of the parotid duct. It may also appear on the hard and soft palate, on the tongue, tonsils, and sublingual glands. In the early stages there is evidence of bleeding (and usually pain) on the slightest touch. A smear stained will show the presence of the typical organism under the microscope. The cases taken early will clear up in from three to seven days. If allowed to develop, pockets will appear between the teeth, with evidence of dead alveolus, and, later, large ulcerative patches on the gums, lips, and cheeks. In the more advanced stages we have extensive areas of necrotic bone, a black gangrene of the soft tissues, and perforations of the cheeks, lips, and hard palate. Last spring I presented several patients at a clinic showing all these latter symptoms without perforations, who had entirely recovered after extensive removal of hard and soft tissues and deep cauterization. But, as a rule, the prognosis is unfavorable.

At this time of writing I have two wards isolated at the hospital. In one, established eight days ago, there are seven patients still under observation; four were entirely free in four days, two on the sixth day, and the seventh I will discharge to-day. In the other ward, established a day earlier, with eight cases, one patient died on the third day, of a double pneumonia; this case was hopeless when I first saw it. In another case there was a partial facial paralysis, and the patient has been operated upon recently for mastoiditis. The angina extended all over the mouth as far back as the soft palate, but will have
been eradicated within a week. Of the remaining patients, all will be discharged within a day or two, except one patient who whooping cough; this will require a few days more. In each case we have had a delicate child to deal with; one with resistance diminished by recent contagious illness. As to diet, all those without elevation of temperature had a reasonable variety; the others only liquids.

In another ward one child has infected its eitritis and another its rectum. I have since had the arms of all bound, to prevent further mischief. The treatment of each of these patients is similar to the oral infection; and both will be discharged within a few days. During the past winter several cases of Vincent’s angina of the middle ear responded to similar treatment, with a greatly reduced solution of trichloracetic acid.

Several months ago I was greatly perturbed by the frequent occurrence (and in one case, recurrence in a discharged patient) of this oral Vincent’s angina in a nursery of runabouts. At last I found a matron violating the hospital rules by feeding several youngsters with the same spoon. After this bit of detective work my worries were over. In another nursery the difficulty was not so easily rectified. A recently admitted child was the carrier, I felt certain. Not until I had ordered all house-cleaning stopped, except with ercolin soaked mops, did further infection cease.

These cases seem most prevalent during the spring and early summer, although I have also seen them during the fall and winter. Fortunately, there are few in private practice; children put out to nurse are rather free, but in several instances they also have been victims.

Conclusions.

To sum up, Vincent’s angina occurs after measles, scarlet fever, whooping cough, and diphtheria—usually in malnourished. It is easily curable if taken early—in the advanced stages, rarely. In the past nine months seven cases advanced to the progressive stages of noma because of our inability to observe the initial lesion; of these, four recovered. We have had nearly thirty others checked in from ten days to a fortnight.1 Young children as a rule do not call attention to their ills; you must be on the lookout for trouble, and not wait for it to be brought to your notice. I have learned this lesson dearly.

44 East Seventy-fifth Street.

THE RATIONAL TREATMENT OF PUSTULAR SKIN DISEASES.

By Jessie Weston Fisher, M.D.,
Middletown, Conn.

A abortory, Connecticut Hospital for Insane.

Modern methods of studying disease have demonstrated that microorganisms play an important rôle in the production of skin affections, especially those presenting pustular lesions, for which type the vaccine or bacterin treatment would seem theoretically an ideal one. The lesions being superficial, the immunizing mechanism is not sufficiently impressed by the invading organisms to produce an immunity.

The natural arrangement of the skin in pavement-like layers of epithelium is such as to form an excellent barrier to the entrance of germs. Otherwise we would all require the constant ministrations of the dermatologist. In its normal condition no organism can penetrate through this structure, but imperceptible breaks in its continuity form avenues of entrance for infection. In addition, the opportunity afforded by the blood stream as a distributing agent for germs must be considered. It is only after the natural defenses of the body are broken down, or the germs are introduced in immense doses, that infection takes place (1).

The introduction of dead bacteria is one method of increasing the defensive powers of the blood, as a reinforcement of troops strengthens a garrison. These sterile bacteria in salt solution constitute what is called vaccine, or more properly bacterin. Vaccine therapy depends for its value upon the production of antibodies which react upon the invading organism either to neutralize their toxins or inhibit their growth. In other words, the patient produces his own antitoxine, with consequent active immunity (2).

As to the method of making the vaccines or bacterins it is unnecessary to go into details here, but they must be carefully prepared, and the heat used in sterilization should not be applied longer than twenty minutes, as much depends upon this point. While autogenous vaccines are unquestionably the most satisfactory, good results can frequently be obtained with the stock vaccines, which should be tried if the autogenous are not obtainable. One must at least be sure of what particular germ, or germs, is the cause of the infection before even stock vaccines are available. The constant occurrences of secondary or mixed infections renders it necessary to have discharges reexamined if healing is not rapid, because immunization against the staphylococcus will not interfere with the growth of streptococci.

While the physician who essays to use vaccines need not necessarily be a trained bacteriologist, he must have a knowledge of the microbes which cause the most common infections. He should have some conception of the principles of immunity. He should know the usual dose of the organisms, and, above all, how to adjust the dose to the requirements of the individual. Each case treated must be a study in itself; personal idiosyncrasies, variations in the virulence of the infection, must all be taken into consideration, never forgetting that the more severe the infection the smaller the dose of vaccine required. There are, of course, limits to the powers of the patient to react to the stimulation of the bacterin. In old chronic sluggish cases the treatment often gives results only after a prolonged succession of inoculations (3).

The most frequent microorganism found in skin affections is the familiar, almost omnipresent, staphylococcus, although the streptococcus is found in erysipelas, the acne bacillus in acne, the tubercle bacillus in tuberculous lesions, and the bacillus of seborrhea in seborrhea. The most common diseases
which are amenable to this treatment are furunculosis, seborrhea, carbuncles, impetigo contagiosa, acne, erysipelas, abscesses, and, possibly, eczema. Dr. T. Caspar Gilchrist (4), who has probably done more work on the use of vaccines in the treatment of skin diseases than any other one man in the United States, says bacteria are of undoubted value in the treatment of all pustular affections of the skin, but especially, in his experience, in the treatment of relapsing furunculosis, staphylococcic dermatitis, syphisis non parasitica, certain forms of eczema, pustular rosacea, and acne.

Acne. The long list of remedies for the treatment of the disfiguring eruption called acne is sufficient evidence of our inability to satisfactionly cope with it, a trifle though it seems. So the patients who are unfortunate enough to suffer from this affection drift from one physician to another, apply gallons of lotions and pounds of salve, finally gravitating to the so called beauty doctor or advertising charlatan. Many physicians do not consider a case of acne worth their serious consideration, so dismiss the patient with a box of cathartic pills and a prescription for a sulphur lotion; thus opening the door to the luxurious apartments of the beauty specialist, who pretends to be doing something even when accomplishing the least; or else the sufferer takes to “Pink Pills for Pale People,” or something equally efficacious advised by well meaning, but meddlesome, friends.

The term acne is generally restricted to designate inflammation in and around the sebaceous glands and hair follicles, which results in small pustules. In acne rosacea there are, in addition, blood vessel changes, which give rise to the well known red appearance. It occurs most frequently between the ages of fifteen and thirty, at a time when people naturally take the most pride in their appearance. There is nothing more unsightly, sometimes even revolting, than a face peppered with pustules and comedones, and this disease has a peculiar predilection for the face. Acne has many names and many phases, varying from the occasional pimple, which annoys the vanity of the society beauty, to the loathsome mass of comedones, pustules, and indurated red masses which leave scars almost as unsightly as the original lesion. Such a condition is very frequent, and, while not dangerous to life, is decidedly uncomfortable and unsightly. In certain employments it is a serious drawback, as it is most objectionable to have these individuals in positions which involve personal contact with others, such as governesses, nurses, house servants, etc. The mortification which the victims of the worst type of acne feel, as a result of their unsightly appearance, is not the least of its annoyances, often resulting in serious nervous symptoms. One young lady patient had been obliged to give up her work, and constantly wore a heavy veil when she went on the street. At the time she began treatment she was so nervous that she would cry if anyone spoke of her disfigurement, and dreaded to meet strangers because they looked at her as though they thought she had smallpox. “Sometimes I could just scream, it is so awful,” she said. Acne rarely persists to any extent after thirty-five to forty years of age, about which time it is apt to gradually disappear, but meanwhile the patients have a number of years in which to hate themselves.

The cause of acne has been variously given as thick skin, sluggish circulation, cold winds, working in oily or dirty occupations, plugging of the orifices of the glands, a lack of personal cleanliness, constipation, intestinal toxemia, dyspepsia, urterine and ovarian diseases, anemia, chlorosis, scurvy, errors of diet, etc., ad infinitum, through the list of ills to which the flesh is heir. While, of course, anything which disorders the metabolic functions must to a certain extent influence any disease, the constant presence of the so called acne bacillus, Unna’s bacillus, or Sabouraud’s bacillus at the base of the comedo proves that the disease is due to bacteriological action. The “blackhead” is not composed of dirt, as commonly supposed, but of degenerated cells and sebum. So long as this bacillus alone is present we find only the comedones or red indurated masses, but when it becomes associated with the staphylococcus it results in pustules, with occasional deep abscesses. The cause, it must be asceded, is this specific organism, often assisted by the staphylococcus, and not alone, as formerly taught, disordered alimentation, ill advised cosmetics, or lack of personal cleanliness. Marcus Haase (5) wonders if we all mean the same disease when we speak of acne vulgaris, but concludes his review of the literature of the bacteriology of acne with the statement that the various organisms described by different observers, from Unna to Gilchrist, as being the etiological factor in this disease, are, in his opinion, simply different phases of the same organism. There is a bacillus constantly present in these lesions, and its pathogenicity is accepted by practically all dermatologists. While he has not seen brilliant results from the use of vaccines, he says the beneficial effects are so marked that he would be loath to treat a patient without their assistance.

The acne bacillus is a short, thick rod, usually retaining the stain with Gram’s method, although occasionally partially decolorized forms may be seen in old cultures which have a granular appearance. It grows best on media to which fresh blood or a bit of fresh animal tissue has been added, and under anaerobic conditions. It takes from three days to as many weeks sometimes to obtain a good culture, which is frequently pink in color. The colonies are elevated, irregular in contour, granular or crumbly, something like the growth of tubercle bacilli. The comedones give the best cultures, and should be transferred carefully to the surface of the medium without rubbing or breaking. By the adoption of this method of procedure pure cultures are invariably obtained. The bacillus is said to be pathogenic for mice and guineapigs. In the treatment of acne we encounter one of the most difficult problems of vaccine therapy, and our failures to obtain good results are, probably, entirely due to improper dose—usually the doses are either too large or too frequent. The tendency of the general practitioner is to increase the dose if he is not getting results, when oftentimes the dose should be decreased. The only fairly accurate way of regulating the dose is by means of the opsonic
index; which is usually out of the question as being too tedious or too expensive to be available. In this particular disease we have a guide which those who run may read; namely, the lesions themselves. If fresh lesions crop out within twenty-four hours after the injection it indicates too large a dose. If no change takes place, or a brief improvement, followed by fresh lesions, it is probable that the dose is too small. If an initial improvement is followed by a crop of fresh lesions, the interval is too long and should be shortened. One of the most frequent errors is in too short an interval, which does not permit time for the development of the positive phase, as shown by a lack of any improvement, or even a progressive retrograde change. This is forcibly demonstrated in those cases which are treated by too large doses of vaccine. The patient, seeing no improvement, but oftentimes finding the condition aggravated, throws up his hands in disgust and abandons the treatment. Later marked improvement may be noted, frequently terminating in complete recovery, when the system has the opportunity to react to the overstimulation previously given.

This was forcibly brought to my notice in a case of severe postular acne, often forming large abscesses, which was under treatment for at least six months, without the slightest improvement. This patient seemed to have an idiosyncrasy to the vaccine, several times getting a systemic reaction in spite of the fact that the dose was reduced to three million acne bacilli, with three hundred million staphylococci, every two to three weeks. The patient was called away on business for six weeks during which time no treatment was taken, returning at the end of that time with great glee to show an improvement of at least fifty to sixty per cent. Thereafter the intervals were increased to six weeks, or until the first fresh lesion began to appear, showing the beginning of the negative phase indicating low resistance. So the case progressed to a complete cure, when there were left only the unsightly scars from previous abscesses. By watching these signs and working the dose up until it just fails to show any "negative phase" clinically, one obtains the maximum benefit of the vaccine treatment in acne. Of course, there are necessarily limits to this method of treatment, but our disappointments in the use of this therapeutic measure can usually be attributed to too much zeal or overdoses. This method of medication will not accomplish miracles, although it sometimes comes near it. It does not in the least interfere with other methods of treatment in acne. The physician can use all the lotions, etc., he desires, but personally I am of the opinion that they do not facilitate matters. Beyond keeping the skin clean by thorough scrubbing with tincture of green soap, the removing of all blackheads as they appear, and steaming daily, local applications seem unavailable. Lovejoy (6) obtained excellent results from doses of three million acne bacilli and one hundred and fifty million staphylococci every five days. Orrill Smiley (7) concludes, after the treatment of one hundred cases of acne vulgaris, that the results are so uniformly good that where one can control the patient, a cure of the condition can be promised in every case. Seborrhea, a chronic disease of the sebaceous glands, is due to a bacillus very similar to, if not identical with, that found in acne, and is very favorably influenced by the use of vaccines. [Fleming (8) and Leon S. Medallia (9)].

Eczema, that protean disease under whose name our ignorance has masked widely different lesions, has been attributed to many different causes, from intestinal toxemia to neurasthenia, but I am inclined to agree with Unna when he states that all these internal causes simply produce a better nutritive basis upon which germs or parasites may develop. In other words, they can only be considered as predisposing factors, which, nevertheless, should be eliminated whenever possible. Unna (10) attributes the disease to a morococcus with which he has produced an inflammation resembling eczema. However, the essential germ has not been isolated, unless we admit that the staphylococcus, which is almost invariably present, is the etiological factor. Many observers agree that the fluid from the unruptured primary vesicle is amicrobic, but that secondary infection is almost invariably present.

Whether it is a primary or a secondary infection, its constant presence keeps up the inflammation leading to deeper or more extensive lesions, so that a rational treatment would be one tending to eliminate this factor of the dermatitis. Hence, whenever an eczema becomes postular, or a microorganism can be isolated from the scales or exudate, vaccine therapy becomes an invaluable adjunct to the treatment, oftentimes effecting a cure without other medication. Usually it is the staphylococcus, rarely the streptococcus, which is the invading organism. Staphylococcus skin lesions, however chronic, are curable by vaccines (11). A personal communication from Dr. James Murphy, of Middletown, Conn., states that a man, for whom we made a vaccine for furunculosis, had suffered for years from eczema. This cleared up entirely under the furunculosis vaccine, the patient remaining well for over a year. The amount of the staphylococcus should not exceed three hundred million at three to five day intervals, while the streptococcus requires only from twenty-five to fifty million to one dose. This treatment need not interfere with any other line of medication, either local or general, of which the textbooks on skin diseases give so many pages from which to choose.

Furunculosis, by which is understood a succession of boils, is a condition which frequently tries the patience of both the doctor and patient, as it did that of Job in prevaccine days. As everyone knows, these painful lesions are due to bacteria, which enter through hair follicles, glands, or slight skin trauma, when through some constitutional derangement the immunizing mechanism is either on a strike, or working on short time. In these lesions we often see most brilliant results when vaccines are utilized as strikebreakers to start the machinery and keep it moving. One or two doses often cause the lesions to dry up rapidly,
and prevent their recurrence by producing an active immunity against the invading organism, which is usually a staphylococcus. Under the use of bacterins the pain disappears within a few hours, and the necessity for a large incision is avoided, as a small opening is all that is required for drainage. The smaller boils usually dry up and disappear without the necessity for opening. The treatment should be continued for several weeks after the active lesions have healed, in order to thoroughly establish an immunity and induce the habit of producing antibodies in the blood of the afflicted individual. Sometimes prolonged treatment is required before permanent immunity is produced. For those subject to boils on slight provocation it is an excellent plan to keep on hand an autogenous vaccine, which can be administered at the first indication of a furuncle, which may then disappear without going through the entire course.

One case of a young woman, who was sent to me (service of Dr. W. E. Fisher) for diagnosis with the suspicion of specific infection, presented numerous dark red, angry indurated areas over legs and trunk. There were no foci of suppuration. The condition was of only a few days' duration, and the patient had a temperature of 101° F. At the suggestion that the condition was one of beginning furunculosis the attending physician was incredulous, but consented to try a stock staphylococcus vaccine. After two days the lesions began to subside, and the temperature to go down. Three doses completed the cure. The Wassermann reaction was negative.

One case (Dr. K. C. Mead) which has not given such brilliant results is that of a young woman who has been under treatment for six months with little permanent improvement. She was markedly improved when she discontinued the vaccine, with a subsequent relapse. There is in this case a family infection, the father, mother, and a sister (who was home only a few days) becoming infected from a common source. Probably a family pot of ointment used in the local treatment of the first lesion, a carbuncle of the father, was responsible. Another case of apparent failure (Dr. J. E. Loveland) occurred in a man suffering from chronic interstitial nephritis who had been tormented with boils for several months before vaccine treatment was instituted, sixty being present at the time vaccine was given. There was a temporary improvement, followed by a fresh crop and subsequent death.

Leary (12), who treated a series of infants suffering from furunculosis, calls attention to the fact that the children not only recovered from boils, but their general nutrition became so much improved after treatment that, from a condition of emaciation, they speedily became the best nourished, and most resistant children in the institution. This has frequently been the case in our series of patients treated by this method; the appetite improves and they gain in weight. Wechsellmann and Michaelis (13) conclude that in the treatment of multiple abscesses in infants, a vaccine is specific.

Carbuncles, which are much more painful than furuncles, frequently producing marked constitutional symptoms, are due usually to the Staphylococcus aureus invading numerous hair follicles simultaneously, producing several centres of necrosis surrounded by areas of inflammation, which are essentially coalesced furuncles. The frequency with which this infection occurs in those individuals whose immunity reaction is at a low ebb, as in diabetes, the aged, etc., is sufficient evidence of the need of stimulating the production of antibodies. The injection of vaccines as soon as the lesion appears works sometimes almost like magic in this condition, unless the responsive power of the patient is at too low an ebb. No crucial incision is required, and the lesion heals with little or no scar. As often happens, these patients do not consult a physician until they have exhausted all the home remedies, when a large necrotic area with numerous openings is found. Vaccines injected at this time have to overcome a greater toxemia than earlier, but even so they are our most powerful allies. The pain usually subsides rapidly, the discharge is often temporarily increased, then the whole necrotic tissue may peel off within twenty-four hours, leaving a clean granulating surface which rapidly heals.

Of course, where the power of the individual to react to the stimuli is lost or very low, as in some cases of advanced diabetes, or where the carbuncle has been allowed to spread, invading large areas, vaccines are usually quite useless. However, they should always be given a trial, even in these extreme cases, for no one can tell when the immunity apparatus is entirely out of commission, and these patients have the right to demand the help that modern science has placed in the hands of the up to date physician. One must remember that carbuncles are dangerous, and the time to get the best results from vaccines is in the beginning, when the subject has the most resistance, not when everything else has failed, and the individual is "down and out." Renal infections, osteomyelitis, acute endocarditis, or general sepsis may follow mild furunculosis or carbuncle. An autopsy made recently on a neglected case of carbuncle, or rather one treated on the expectant plan (namely, expecting nature to do unaided what might have been another story, if the patient had been given the benefit of vaccine treatment), showed an acute endocarditis, acute nephritis, and general septicemia, all due to the Staphylococcus aureus, the same germ as that found in the carbuncle.

Erysipelas.—True erysipelas, as all are aware, is due to the infection of the lymph spaces of the skin by the Streptococcus erysipelas. It may involve the cellular tissue, and always gives rise to constitutional disturbances. The experimental evidence goes to show that the offending organisms do not escape into the circulation, but that the pyrexia, etc., are due to the absorption of specific toxins. Ross and Johnson (14) in a series of fifty cases treated by vaccines alone found that the change in the patients after the first dose of vaccine, in twenty-four to forty-eight hours, was most striking. The temperature dropped from 110° to 3°, delirium subsided, and the patient felt infinitely better. The duration
was much shortened, complications did not occur; the color of skin was less angry; and the tenderness and swelling lessened. They say that a "vaccine prepared from the Streptococcus erysipelatis, properly administered, exercises a specific and controlling influence on the course of the disease, preventing its spread, lessening its severity, and hastening recovery."

The few cases which have come to my notice fully corroborate their conclusions, but in this condition much better results are obtained if the vaccine is administered as soon as a diagnosis is made, not as a last resort when all else has failed, and the patient is in extremis, without power to react to the stimulus. The guide to dose is found in the severity of the infection and the clinical response of the patient. "The more severe the case and the less satisfactory the clinical response, the smaller the dose." The treatment should be instituted with a polyvalent stock vaccine, which is, if possible, exchanged for an autogenous one later, giving 1,000,000 in severe cases, and double that if the case is seen early, when symptoms are milder. If the case shows no improvement in twenty-four hours, administer five million, but if improvement is noticeable, repeat the initial dose, which is then gradually increased to twenty or forty million, given every forty-eight hours, until a week or ten days after the temperature is normal, and the bluish has disappeared, showing that immunity has been completely established. *Impetigo contagiosa* is characterized by successive corps of flat pustules, due to infection by staphylococi, usually through the agency of firm nails from scratching. It is most frequently found in children, who are in intimate contact. The children affected are usually cachetic and poorly nourished. Sometimes streptococci have been found in the epidemic form. These cases respond admirably to vaccine therapy. If the staphylococcus is found, the initial dose should be three hundred million, increased to five hundred million, given every three days. If the streptococcus is the offending agent, begin with twenty-five million, increasing to fifty million, which is continued at augmented intervals up to five days, for one month after the last pustule has disappeared. These children show rapid improvement, not only in the skin lesions, but by a gain in weight and general nutrition. It would be too time consuming to detail individual cases, for which reason reference to them has been omitted; but suffice it to say that I have made vaccines for some four hundred cases, including many of each of the above named skin diseases, and the results have been so uniformly good that there can be no doubt of the value of this method.

**SUMMARY.**

There is no doubt that in purpuric skin diseases vaccines are specific when given in proper doses. That they not only act as a specific upon the lesions themselves, but that they improve the general nutrition and resistance of the patient. That the condition of the surface lesions is a sufficient guide for dose without the necessity for taking the opsonic index. In erysipelas the early use of vaccines shortens the course, relieves constitutional symptoms, and prevents complications.

**DOUBLE DRAINAGE TUBES (INNER AND OUTER) FOR NARES AFTER SUBMUCOUS RESECTION OF THE SEPTUM.**

By SAM GOLDSTEIN, M.D., New York.

This simple contrivance for use with pressure splints, after submucous resection of the septum, has proved an advantageous addition to my technic. Of greater import, however, is the resulting comfort afforded the patient, until the dressing has been removed by the operator, in consequence of the free nasal respiration secured.

These drainage tubes are inexpensive, and of the simplest construction (Figures 1 and 2.) The larger or outer tube is vulcanized rubber, and the smaller, or inner, soft gum tubing; the latter fitting in the outer tube snugly enough to remain in situ, and at the same time sufficiently loose to permit the attendant, or the patient himself, to remove the same whenever it becomes occluded, without disturbing the position of the vulcanized outer tube or displacing any of the packing in the nases.

The dimensions of the outer tubes, which I have found most suitable, are about 1½ to 1½ inches in length, 5/16 of an inch in bore, and about
1/16 of an inch in thickness. The soft gum inner tubing should have about a 3/16 inch bore, and protrude for a short distance, especially at the proximal end, for easy removal from the outer tube. It is advisable to have the inner and outer tubes of different colors, to avoid the patient's erroneous removal of the outer tubing, when he wishes to cleanse the inner one.

My usual procedure, after completing the septal resection and replacing the cartilage, is to place a properly shaped piece of paraffin wax sheeting against each septal mucosa, then adjust the double drainage tubes on the floor of the nares, and fit all above and external to the tubes pieces of Bernay's sheets, and moisten these.

The vulcanized outer tubes may be shaped into any form desired, by placing them in hot water to soften, and patteming them to the configuration of the nares.

1211 Madison Avenue.

THREE CASES OF ACUTE GASTROINTESTINAL INTOXICATION WITH Constipation and a Suggested Method of Surgical Treatment.

BY R. J. MANION, M.D., C. M. (TORONTO); L. R. C. P. AND S. (EDIN.),
Fort William, Ontario.

The writer has had the misfortune during the past three years of attending three cases, all fatal, the outstanding features of which were a very acute onset of severe acute intoxication as to cause coma, absolute constipation, vomiting of black material, and death in from one to three days. The constipation was so absolute and the vomiting so intractable as to resemble an obstruction of the bowels, but the ante mortem findings in one case, and the post mortem findings in the other two, revealed no sign of organic obstruction, but only a paralysis of the ileocecal portion of the small intestine, above and below which the bowel was absolutely normal. And despite the fact that the material in the distended, paralyzed portion of bowel could easily be forced in either direction, nature, even with the assistance of oil, salts, and so forth, was quite unable to overcome the obstruction caused by this paralysis, with the result that the distended portion acted as a reservoir of toxins from which the body absorbed enough poison to cause ultimately a fatal ending.

CASE I. Baby D., the thirteen month old son of a low physician, was taken suddenly ill on July 15, 1910, with vomiting of black material, absolute constipation, and coma. Bowel irrigations were tried with no effect; the stomach was washed with temporary relief of vomiting; castor oil and small doses of calomel and salts were given with one small bowel movement as the result. Three physicians and the writer were in attendance, and one insisted that there was an obstruction of the bowels, although the abdomen was quite soft, and on examination there was no sign of obstruction. Thirty-six hours after the onset the abdomen was opened as a last resort, the operators finding no organic obstruction, but a dilated part of small intestine proceeded by a collapsed portion through which the contents of the dilated portion could be easily pushed with the fingers. The holly was closed, and purgation with heavy doses of salts tried fairly successfully, but the baby died ten hours later.

CASE II. Baby T., aged ten months, became ill on June 2, 1911, with vomiting of black material and constipation except one black movement three days. The writer was called at 2 p.m. on June 4th, two days after the onset of the illness. On inspection the baby was found collapsed; hands and feet cold, face covered with cold sweat, temperature 95° F. The stomach was washed, and the bowels irrigated with no result. Calomel, one grain, in divided doses, given; followed by salts, one drachm. The infant died at 7 p.m., five hours after first visit of the physician. After much pleading the writer was allowed to open the abdomen, and find the stomach and upper intestine distended with fluid and the ileum collapsed. There was no organic obstruction.

CASE III. Baby C., aged six months, male, rather weakly constitution, was taken ill at a summer resort on June 29, 1913. The mother, temporized for two days, giving castor oil with, she said, good effect, but on the morning of June 31st the infant became comatose, and was rushed to the city, arriving at 10 a.m. The writer was called and found the baby unconscious, temperature 97° F., pulse 120, respiration 5. It appeared to be dying, and the mother had feared not arriving in time to have a physician see it alive. An intragastric saline injection was immediately given, some brandy by the mouth as vomiting had not yet begun, and calomel, one grain, repeated, with no result. Intragastric injections were repeated, brandy and doses of strychnine given with a good reaction; the respirations coming up to normal, pulse from 96 to 100, temperature 98° to 101° F., by the following day. The bowels, however, refused to move, and black vomiting began. The stomach was washed and one half ounce of salts left in, which treatment was repeated in a few hours with no bowel movement resulting. Irrigations of the bowel and enemas of salts were also ineffectual. The baby was kept alive four days by intragastric stimulants, stomach and bowel lavage, and stimulants, but did not regain consciousness; had no motion of the bowels, and died on July 4th. The parents readily agreed to an autopsy. The stomach, duodenum, upper jejunum, and lower ileum were normal, but some two feet of lower jejunum and upper ileum were markedly distended with black fluid, similar to the vomitus.

The three cases reported are the only ones of this kind encountered by the writer among some hundreds of cases of summer complaint treated in the past eight years. They were all artificially fed, all males, and all occurred in early summer. There appears very little in the ordinary textbooks on this somewhat rare condition, Still's Common Disorders and Diseases of Children and Osler's Modern Medicine not mentioning it, but Holt in his second edition, p. 365, gives sixteen lines to it.

Conclusions. Taking into account the gravity of this condition, the writer takes the liberty of drawing the following conclusions from this small series of cases:

The treatment should consist of intragastric injections, stimulants, irrigation of the bowel and stomach, and strong purgation, for, as Holt says, "in a condition of this kind diarrhea is a conservative process of the greatest possible value." But if it were found impossible to satisfactorily evacuate the bowels of the patient, it is the opinion of the writer that a laparotomy would be indicated with the object of forming an artificial anus to drain the distended portion of bowel, which is nothing more or less than a toxic reservoir, absorption from which is gradually killing the patient. The whole operation could be done inside of ten minutes without even the shock of an anesthetic if the patient were unconscious, as he usually is in this condition. And the artificial anus could be attended to after recovery from the acute condition.
Questions for discussion in this department are announced at frequent intervals. So far as they have been decided as to form, the further questions are as follows: CXXXVII.—How do you treat threatened abortion? (Closed August 15th.)

CXXXVIII.—How do you treat insomnia? (Answers due not later than September 15th.)

CXXXIX.—How do you treat chancre? (Answers due not later than October 15th.)

Whoever answers one of these questions in the manner most satisfactory to the editor and his advisers will receive a prize of $25. No importance whatever will be attached in literary style, but the award will be based solely on the value of the substance of the answer. It is requested (but not required) that the answers be short, if practicable no one answer to contain more than six hundred words; and our friends are urged to write on one side of the paper only.

All persons will be entitled to compete for the prize whether subscribers or not. This prize will not be awarded to any one person more than once within one year. Every answer must be accompanied by the writer's full name and address, both of which must be at liberty to publish. All papers contributed become the property of the JOURNAL. Our readers are asked to suggest topics for discussion.

The price of $25 for the best essay submitted in answer to Question CXXXVI has been awarded to Dr. Nelson Du Val Brecht, of Washington, D. C., whose article appears below.

PRIZE ESSAY CXXXVI.

THE TREATMENT OF CHOLERA INFANTUM.

Dr. Nelson Du Val Brecht, of Washington, D. C., states that:

Considered from the standpoint of etiology cholera infantum may be classified into:

(a) The infectious forms; and

(b) The mechanical irritative forms, due to improper food (Booker). The infectious forms comprise those in which the source of infection is external to the body (ectogenous) and those in which the elements of infection are intrinsic (endogenous) (Escherich).

The therapy resolves itself into prophylaxis and curative treatment.

Prophylaxis.—In hot weather infants should receive an abundance of fresh air and be kept scrupulously clean by frequent bathing. They should be carefully protected from flies, which not only cause restlessness and irritation but act as carriers of infection. If possible, especially during the months of July and August, they should be taken to the seashore or mountains, and when this is impossible good substitutes are found in the day excursions, and summer camps established for children by municipalities and charitable societies. The child should be given an abundance of cool boiled water to drink and the clothing should be light and comfortable, without restricting bands or buttons. In hot weather overfeeding is to be condemned, and weaning should not be attempted. The bowels should be regulated, and constipation avoided. In the case of bottle fed infants the milk should be delivered from a reliable dairy twice daily, should be sterilized or pasteurized, and should be kept in a refrigerator until needed for use. The intervals of feeding should be regular. If any milk remains in the nursing bottle after a meal, it should be discarded. It seems hardly necessary to mention that the old-fashioned nursing bottle with the long rubber tube should never be employed. The nursing bottles when emptied should be filled with a saturated solution of sodium bicarbonate, allowed to stand several hours, and then scalded or washed externally and internally with a bristle brush. Rubber nipples must be sterilized daily. Breast nipples should be washed before and after each nursing with a saturated solution of boric acid. If there is caking of the breast or a fissured nipple, the condition should be cured before permitting the infant to nurse from the previously affected gland. Re-infection occurs much more frequently in hospitals than in private practice, because there is a lack of care in handling the diapers and in preparing the food by nurses, who are in proximity to many patients.

Curative Treatment.—The therapeutic indications are:

1. To combat bacteria. 2. To rest the gastrointestinal tract. 3. To relieve anhydremia. 4. To stimulate and prevent collapse. 5. To aid convalescence.

1. The intestinal flora in these cases has been demonstrated to consist of the Shiga bacillus (Bacillus d'enteria), the Streptococcus enteritidis, the Bacillus pyocyaneus, various strains of the Bacillus coli and the proteolytic bacteria such as the Bacillus subtilis, Bacillus mesentericus vulgaris, and the Bacillus tyrotrix tenus. The most rational measure to be pursued, when circumstances permit, is to endeavor to identify the invading microorganisms by examinations of the stools and the blood. After such identification, the use of appropriate bacterial vaccines or phylacogens is indicated. In establishing the dose of bacterins or phylacogens for children, either Young's or Cowling's rule may be followed with advantage.

While we cannot sterilize the alimentary canal, we can to a large extent inhibit bacterial growth, and limit fermentation and putrefaction, by the use of intestinal antisepsis, administered by the mouth or in the form of rectal irrigations. Salol, bismuth salicylate, aromatic sulphuric acid, phenol, beta-naphthol bismuth, phenol sulphocarbonate, silver nitrate, quinine sulphate or bisulphate, and calomel are all useful drugs of this class. As a routine measure one grain of calomel should be administered three times during the first day of treatment.

2. Our means of securing rest for the gastrointestinal tract consist in: (a) Withholding of food and modifying the diet; (b) checking diarrhea, and (c) relieving or preventing emesis.

(a) When symptoms of gastroenteritis become manifest, milk should be discontinued. For the first twenty-four hours the baby should be sustained by the use of a solution of egg albumen, ice, peppermint tea, black tea, and cool water. After the first day a selection of any of the following preparations as nourishment may be made, i.e., barley gruel, oatmeal gruel, albumen water, gum arabic water, cold tea, lime water, toast water, bread water, mutton broth, cornstarch pap, burnt flour ecup, acorn cocoa, beef juice, dextrinized gruel.
Liebig's soup mixture, whey, panopeptone, scraped beef, liquid peptonoids, and lozenges of quinine tannate with chocolate. Children like the taste of the last preparation.

(b). Useful prescriptions for checking the diarrhea are:

R Bismuthi subcarbonatls, .......................... 5 j
Arm cinnamomi, ...................................... f 3 j.
M. Sig.: A teaspoonful every one to two hours.
R Argenti nitris, ....................................... gr. ii
Arm destillatae, ........................................ f 3 j.
M. Sig.: A teaspoonful every two hours. (To be dispensed in a dark bottle with a "shake" label.)
R Resorcini, ............................................ gr. ii
Arm cinnamomi, ........................................ f 3 j.
M. Sig.: A teaspoonful every two hours.
R Bismuthi subnitris, ................................. 5 j—jv;
Salolis, .................................................. gr. xxiv;
Mixture cretes, ........................................ f 3 j.
M. Sig.: A teaspoonful every two hours.

(c). For excessive vomiting, gastric lavage is per os, the best single remedial measure. In some cases the following may be administered:

R Tinutre iodidi, ........................................ gtt.s x;
Arm menthae, viridis, q. s. ad. ........................ f 5 j.
M. Sig.: Fifteen drops every hour.

3. When the course of the disease is rapid and prostration ensues, hypodermoclisis or enteroclysis is indicated. The Cantani normal salt solution should be employed: epinephrin chloride solution may be added with advantage.

4. When stimulation is required, caffeine, strychnine, and camphor are useful to supplement enteroclysis and hypodermoclisis. Hot baths and the use of hot water bottles are often of great value, if the peripheral circulation is feeble or collapse threatens.

5. During convalescence milk feeding must be resumed gradually. When a tendency to loose stools persists astringents must be continued. The judicious use of tonics and hematincs materially hastens complete restoration to health.

Dr. Charles T. Leslie, of Pittsfield, Mass., says:

Given an artificially fed child of about six months of age, fairly well developed and nourished, but which has had at some previous date a digestive disturbance, and is now suddenly made ill with persistent vomiting of everything taken, severe diarrhea at first fecal, then loose, with curds and foul smelling, later watery and profuse, perhaps blood streaked, the rectal temperature elevated—103° F., or higher—very restless and having evident pain, sunken eyes, and fontanelles receding. Such a case of cholerlta infantum, with its extreme prostration, needs careful, energetic, and immediate treatment. If we could have induced the mother to have kept the child at the breast, more than likely this condition would not have developed; or if we could have taught her to maintain the feeding periods as near the normal and normal as possible, and to avoid any sudden changes in the quantity or quality of the food, not to pasteurize the milk or add to it any disinfectants, but to use only pure, clean fresh milk, probably the child would have escaped. But if infection has occurred (with the Shiga bacillus for instance) we must give our attention, by way of treatment, to the gastro-intestinal tract, to the nervous system, to the circulation, and to furnishing the infant body with fluids to take the place of those lost through the diarrhea and vomiting.

The gastro-intestinal tract.—To give it physiological rest, stop all food for the first twenty-four hours or so. Give water, plain boiled, only in drachm doses, with one tenth of a grain of calomel for about ten doses, every half hour—to clean out the intestines; it also has some germicidal value. Castor oil or phenolphthalein may be used, but I prefer calomel. Catharsis is assisted by irrigation of the lower bowel, two or three times in the first twenty-four hours with some unirritating solution. Normal salt solution is as good as anything. Sometimes gastric lavage is indicated to lessen the vomiting. On the second day, when feeding can be started, try the white of an egg at long intervals, or whey, or barley water, or buttermilk, especially the last (to which may be added cane sugar to sweeten). Buttermilk contains many bacteria whose activity in the intestines is antagonistic to the organisms causing the infection. There is a tablet on the market which, when given every two hours, acts in the same manner; it contains the Bacillus lactis bulgaricus in pure culture.

Breast milk, when it can be obtained, is most desirable, furnishing both food and an antitoxine. Gradually return to the former or a proper diet as the symptoms abate. For the nervous system nothing is so beneficial as morphine, grain 1/50, and atropine, grain 1/500, repeated in one hour if needful. Morphine also helps the heart and combats shock. If the stomach will retain it, a few drops of brandy will serve to stimulate the circulation. Strychnine sulphate is sometimes useful. To replenish the fluids lost to the body through the liquid stools and vomiting, normal salt solution, given in a systematic manner, i.e., three or four ounces under the skin, every four hours, as seems necessary. Normal salt solution may be given in a high enema if it will be retained. Do not be alarmed if the kidneys seem to have stopped all their activity. Fresh cool air and careful nursing are necessary adjuncts to a happy recovery.

Dr. Joseph R. Wiseman, of Syracuse, N. Y., holds that:

The best way to treat cholera infantum is to prevent it. The disease does not depend upon bacterial infection, but is an acute toxemia due to the depressant action of heat, which directly injures the infant's vital powers and lowers its tolerance for food. A slight error of diet, which in cooler weather would cause but little disturbance, may produce severe or fatal illness. All artificially fed babies are at best contending with a food poorly adapted to their physiological needs, hence they are more likely to be injured by the same degree of heat than are breast fed babies. Many infants, particularly among the lower classes, begin the summer with chronic disturbances of digestion. These infants are particularly susceptible to the effects of heat. Infants with lowered food tolerance are more apt to be unfavorably affected by milk of high bacterial content, and hot weather complicates matters by favoring a luxuriant growth of the milk bacteria.
Cholera infantum may be considered an “enterogenous coma,” analogous to diabetic or uremic coma. It is caused by exceeding the infant’s limit of carbohydrates and salts. The food which formerly caused the baby to thrive now acts as a rank poison. There occurs a profound disturbance of intermediary metabolism with the accumulation of toxic products in the blood, and the presence of a true acidosis.

How, then, may we prevent cholera infantum? Keep the infant as cool as possible during hot weather. Give frequent drinks of cool boiled water between feedings, and several cool baths daily. Clothe the infant as lightly as is consistent with safety. Treat promptly every slight disturbance of digestion. Send babies into the country whenever possible, for even though the heat may be as great, there is more chance for radiation (breezes, lack of heat stagnation) and they do infinitely better. Even daily outings are of considerable help. Pure milk is of course essential, but alone will not solve the problem. Infants fed upon condensed milk, which is supposed to be sterile, are particularly subject to summer diarrhea. Milk stations are of great assistance, largely by the instructions given to mothers and the inspection of home conditions by nurses. If the purity of milk or the facilities for its storing are not above question, boil it just before using. On hot days dilute the feedings up to one half with boiled water. Above all, encourage breast feeding and delay weaning until cool weather.

The first essential in treatment is absolute starvation for twelve to twenty-four hours. The infant should be given as much water or very weak tea as possible, sweetened if necessary with saccharin (grain 1/6 or 1/2 to the quart). If diarrhea is profuse no cathartic is needed. With insufficient evacuations give ten 1/10 grain calomel tablets, at ten minute intervals to a child of one year, followed by two or three teaspoonfuls of castor oil. For free vomiting the stomach should be washed out once or twice. If vomiting continues, absolute rest must be given for several hours. With great loss of fluid through diarrhea or vomiting, weak physiological saline solution should be given by the rectum, by the drop method if possible, otherwise by subcutaneous infusion, half a pint every twelve hours.

With high fever, severe toxemia, or profound involvement of the nervous system, hydrotherapy is of signal benefit. The infant should be put into a tub of water at 90° F., after bathing the face and head with cold water. Gentle friction should constantly be made while ice water is poured in slowly on the side furthest from the child’s body until the temperature of the water falls to 80° F. Agitation of the water and friction should be continued for five to ten minutes if well borne. A wet pack may follow the bath, or be used as a substitute. A folded sheet or towel is wrung out of water at 65° to 70° F., and laid upon a dry blanket. The child is wrapped in the damp sheet around which the blanket is snugly tucked. The pack may be continued one half hour or longer, and may be repeated every four hours. After removal the trunk should be gently rubbed with a cloth wet with water at 70° F., and dried.

Drugs are of limited value. To neutralize the effect of the poison upon the heart and nervous system the hypodermatic injection of morphine, grain 1/50 and atropine, grain 1/600 to a child of one year, sometimes has a decidedly beneficial effect. It may be repeated in one or more hours as needed. With the presence of drowsiness, stupor, or slight diarrhea, opium in any form is contraindicated, but for excessive vomiting, purging, great restlessness, or pain it is often valuable. Medicinal stimulants are of doubtful utility but should be tried in severe cases. Hypodermics of caffeine, strychnine, camphor, or brandy are probably the best. With a persistence of diarrhea large doses of bismuth subcarbontate are useful, five to ten grains suspended in mucilage of acacia, and given every two hours.

At least by the end of twenty-four hours, whether or not the condition of the patient is satisfactory, food must again be given. A hunger cure is a two-edged sword, and although essential for a brief period to free the organism from toxemia and to diminish fermentation, each additional hour of starvation lessens the tolerance for subsequent nourishment. Of foods which have the greatest power to raise the infant’s limit of tolerance, human milk and albumin milk (Finkelstein) take first rank. Wet nurses are unfortunately very scarce. Albumin milk (a suspension of precipitated casein in buttermilk with the addition of sugar) is practically limited to hospitals or very intelligent private nurses because of the difficulty of its preparation. In most cases, therefore, we have to rely upon the more common milk preparations. Of these buttermilk is probably the best, because of its low fat and carbohydrate content and its high percentage of salts. Skimmed milk, or one half milk and dillent may be used. In place of buttermilk a lactic acid bacilli tablet, dissolved in each feeding, may be tried. Broths and whey are usually not indicated. Whatever food is used the carbohydrate content must not fall below a minimum of 25 per cent., otherwise the tissues will lack the power to bind the ingested water, and no gain in weight or an actual loss will follow. If sugar is added, maltose-dextrin preparations are probably the best. Milk should be boiled before using, to prevent a secondary intestinal infection.

Whatever food is chosen, including human milk, must be given at first in very small quantities and at frequent intervals. One may begin with one to two ounces of milk the first day and increase to three ounces in two or three days. Ten feedings in twenty-four hours should be given, and not until the total quantity of milk reaches ten ounces should the intervals be made longer. The quantity and strength of the food must be increased with sufficient rapidity to prevent inanition and further weakening of the infant’s vital powers, yet, the limit of tolerance must not be exceeded lest a fresh catastrophe result. One is thus between Scylla and Charybdis. The general condition and behavior of the infant are a much better guide than the stools alone. If the infant shows itself sensitive to the food chosen, when given in small amounts, starva-
tion should not be repeated, but a change of diet made. Only in the presence of symptoms of intoxication on a fairly full diet should a renewed restriction of food be ordered.

It must not be forgotten that a continuance of fever and diarrhoea may be due to infection, either intestinal—bacillus of Shiga (Bacillus dysenteriae), Salmonella cholerae suis, streptococcus; or parenteral—bronchitis, bronchopneumonia or otitis media. In this case a second hunger cure might be fatal.

Fresh air is of great advantage. Even with high fever and toxic symptoms the babies should be allowed to rest outdoors.

(To be continued.)

Therapeutic Notes.

Treatment of Chorea Minor.—Binz, in Zentralblatt für die gesamte Therapie for May, 1912, is credited with the following formula for use in chorea:

R  Sodii arsenatis exsiccati, gr. ½ to 1½ (0.01-0.03 grammes); Antipyrina, gr. ⅛-⅛⅛ (5 grammes); Syrupi aurantii, s. d. (50 grammes); Quinina sulphatati, gr. ⅛ to ⅛⅛ (150 grammes).

M. Sig.: One teaspoonful three times daily after meals.

R  Extracti cannabis indicae, gr. ½ to ⅛ (Gr. v); Arsenii trioxidi, gr. ⅛ to ⅛⅛; Quinina sulphatis, gr. ⅛ to ⅛⅛; Valerianae, q. s.

Divide in pilulae No. xxx.

Sig.: One pill three times daily after meals.

Treatment of Exophthalmic Goitre.—Cas-taigne, Gouraud, and Paillard, in Journal médical français for March, 1913, state that while the drug treatment of exophthalmic goitre has generally been exclusively symptomatic, two substances—other than organic extracts—seem to exert a more general action on the disease.

Sodium salicylate has recently been taken up by Babinski in these cases, and he advises its use particularly in cases where the disturbance is of infectious origin, e. g., after acute rheumatism. The patients to whom the salicylate was administered showed a rapid diminution of the characteristic symptoms and the size of the thyroid, as well as a general constitutional improvement. The drug is prescribed thus:

R  Sodii salicylates, gr. xii (0.75 gramme); Sodii bicarbonatis, gr. iv (0.25 gramme).

Ft. in cachetam no. i.

Sig.: Four cachets a day, to be taken with the meals.

The salicylate treatment should be continued a month, intermitted, then resumed.

Quinine sulphate has been advised by Lancereaux and Paulesco, with the object of inducing vasocostriction of the thyroid vessels. The average dose is fifteen grains (one gramme) to be taken with the evening meals in two doses, a quarter of an hour apart. Huchard combined quinine hydrobromide with an aqueous extract of ergot—½ grain (0.1 gramme) of each in a pill: six to eight pills to be taken during the day.

Digitalis is indicated where there is cardiac insufficiency with dilatation of the right ventricle. If used for tachycardia or palpitations its effect is uncertain, and there is a possibility of harm resulting.

Strophantus has been advised instead for the palpitations.

Tremor, when intense, may be treated with tincture of belladonna or hyoscyamus. Atropine or scopoline, 1/120 grain (0.0005 gramme) o. e. ther., might also be used, but a close watch must be kept over the patient.

Restlessness and insomnia should be treated with mixed bromides, valerian, sulphonmethanum, diethylmalonylurea, or chloral hydrate.

Arsenic is generally poorly borne, but subcutaneous injections of sodium cacodylate have proved useful in certain cases.

Kocher advises the administration of sodium phosphate on the ground that thyroidectomized animals become cachectic when sodium phosphate and magnesia are removed from their food.

Some observers have found calcium chloride useful in exophthalmic goitre. It may be given as follows:

R  Calcii chloridi, iiss (10 grammes); Syrupi aurantii flavo, 3v (20 grammes); Acqua destillata, o. s. ad 3v (150 c. c.).

M. Sig.: Three tablespoonfuls daily.

Treatment of Coryza Due to Chemical Irrita- tion.—G. Laurens, in Journal de médecine de Paris for May 3, 1913, is credited with the following combination, to be used where severe and obstinate coryza results from irritation of the mucous membranes by chemicals:

R  Sodii sulphati, gr. lxxv (5 grammes); Glycerini, 5iss (75 grammes); Acqua destillata, 5vi (25 grammes).

M. F. solutio.

One teaspoonful of this solution is to be placed in a quart (litre) of normal saline and used as a nasal douche twice a day.

The following ointment may be drawn up into the nose:

R  Eucalyptoli vel camphorae, 1 or gr. iiss (0.15 grammes); Acidi borici, 5vi (4 grammes); Petrolati, 5v (20 grammes).

M. ft. unguentum.

Treatment of Heartburn in Pregnancy.—J. B. Hart, in his recently issued Guide to Midwifery, states while heartburn is a very common symptom in pregnancy, it demands attention, since there are always suspicions that it may prove a persistent condition. It may also indicate that in the later stages of pregnancy albumin will appear in the urine.

The patient should be given ten drops of the B. P. saccharated lime solution in each glass of milk she takes. The lime solution in question is made by shaking calcium hydroxide with a solution of refined sugar and allowing the excess to settle, and contains the equivalent of about eight grains (0.5 gramme) of lime in each fluid ounce (30 c. c.).

The following preparation should also be adminis-

R  Bismuthi sulfuratis, gr. x (0.6 gramme); Sodii bicarbonatis, gr. xi (0.4 gramme); Pulveris rhei, gr. ii (0.13 gramme).

Fiat pulvis. Mitte tales no. xxiv.

Sig.: One powder, thrice daily after food, in a wafer moistened with water.
Treatment of Hyperidrosis and Bromidrosis.—

Fortouquet, in *Monde médical* for December 5, 1912, is credited with the following formulas for use in hyperidrosis of the scalp:

- **R**. Soda boratis, .......... **3**ss-i (15-20 grammes);
- Camphora, .......... **3**v (1 gramme);
- Aetheris, .......... **3**ii-lx (10-30 grammes);
- Acque destillate, .......... **3**vi (250 grammes).

**Fiat lotio.**

**Sig.: Use as a wash every evening.**

Hydrargyi chloridi corrosivi, .......... **3**i (0.2 gramme);
Acidi tartarici, .......... **3**ii (5 grammes);
Acidi salicylici, .......... **3**ii (5 grammes);
Spiritus lavandule, .......... **3**iii (5 grammes);
Oleii rosmarini, .......... **3**i (125 grammes);
Alcoholis, .......... **3**viii (250 grammes).

**Fiat lotio.**

**Sig.: Use as a wash every morning.**

In hyperidrosis of the axillae and genital folds, frequent warm baths should be taken, and the parts washed with dilute alcohol:

- **R**. Alcoolis absoluti, .......... **3**v (20 grammes);
- Acque destillate, .......... **3**v (25 grammes).

**Misc.**

One of the following dusting powders should then be applied:

- **R**. Camphora, .......... gr. xv (1 gramme);
- Talc., .......... **3**iii (10 grammes);
- Magnesi oxid, .......... **3**x (40 grammes);
- M. ft. pulvis.

- **R**. Talc., .......... gr. lxv (5 grammes);
- Potassii permanganatis, .......... **5**ss (10 grammes);
- Esmarethi subnitratis, .......... **5**i (25 grammes);
- Amyl, .......... **5**i (60 grammes);
- M. ft. pulvis.

In bromidrosis, not only should the excessive perspiration be overcome with the preceding preparations, but the feet should be washed with a solution, containing five drachms (twenty grammes) of sodium borate and a tablespoonful of tincture of benzoin to the quart (litre). Dilute formaldehyde lotions or Cologne water may also be used.

The following combination has been recommended for bromidrosis by Eschoppé:

- **R**. Betanaphathol, .......... gr. xv-xiv (1-3 grammes);
- Olei thymi, .......... **m**xlv-bxxv (3-5 grammes);
- Acide hypophosphorosi dilutii, .......... **5**i (5 grammes);
- Cupri sulphatis, .......... **3**ss (15 grammes);
- Zinci sulphatis, .......... **3**i (45 grammes);
- Acque destillate, .......... **3**v (2500 grammes).

**Misc.**

As dusting powders boric acid, or boric acid and starch in equal parts, have been recommended; likewise the following:

- **R**. Acidi salicylici, .......... gr. lxv (5 grammes);
- Alumini, .......... **3**ss (45 grammes);
- M. ft. pulvis.

**Pituitary Extract in the Treatment of Hemoptysis.—** E. Rist, in *Bulletins et Mémoires de la Société médicale des hôpitaux de Paris*, April 24, 1913, states that, inspired by the experimental work of Wiggers, he tried intravenous injections of an extract of the posterior lobe of the hypophysis (pituitrin) in twelve cases of abundant—though not "fulminating"—hemoptysis, with most excellent results. The dose used was 0.5 c. c., and the injections were made into a vein at the elbow. Whereas ice and morphine had proved ineffectual, the injection of the pituitary preparation was followed almost immediately by cessation of the hemmorrhage in ten out of the twelve cases. The patients continued to expectorate blackish material for a few hours, but the flow of fresh blood was clearly arrested by the remedy. Where the hemorrhage recurred on succeeding days, the same prompt relief was obtained. In the eleventh case the first injection alone proved effectual, while in the twelfth the first injection, though soon successful in its results, at first caused sudden pallor, vertigo, and a rise of blood pressure from 80 to 95 mm., with primary increase in the amount of hemorhage for two or three minutes. Rist thinks such phenomena can be avoided by diluting the remedy with a few cubic centimetres of saline solution and injecting very slowly.

P. Emile Weil, discussing Rist's communication, pointed out that in 1909, with Boyé, he had shown that extracts of the posterior pituitary lowered the coagulation time of the blood where this was increased. Livon soon after found the coagulant properties of the extracts were so intense that no blood pressure tracings could be taken from the dogs experimented on, the blood at once clotting in the cannule. Weil believed the results obtained by Rist to have been due rather to this coagulant action than to the diminished blood pressure in the pulmonary circulation noticed by Wiggers in his experiments.

**A Gynecological Hint.—** Ralph Waldo, in the *International Journal of Surgery* for February, 1913, refers to the fact that granulations, or small mucous polypi, often form in the lower portion of the female urethra, causing frequent and painful urination. They can easily be removed after the free application of a two per cent, cocaine solution. As they are usually associated with urethritis, this must be cured by appropriate treatment; otherwise the growths will return. Not infrequently Skene's glands are infected, and to remove the infection it is usually necessary to incise the small ducts (two in number) leading to them.

**Uses of Balsam of Peru.—** Deffuant, in *Journal de médecine de Paris* for May 17, 1913, is credited with the statement that while balsam of Peru may be directly injected into abscess cavities or applied on cotton or gauze, ointments may also be used in the treatment of sluggish ulcerations and sinusse.

Van Hoffer and Gratz recommend the following combination:

- **R**. Argenti nitritatis, .......... gr. v (0.3 gramme);
- Balsami peruvianii, .......... **5**ss (6 grammes);
- Unguetti, .......... **3**ii (90 grammes);
- M. ft. unguentum.

Cassini has been using for a number of years the following:

- **R**. Argenti nitritatis, .......... gr. xv (1 gramme);
- Balsami peruvianii, .......... **5**ss (50 grammes);
- Emplastri, .......... **5**ss (200 grammes);
- M. ft. unguentum.

In the treatment of burns, Gaston and Guillet employ this combination:

- **R**. Balsami peruvianii, .......... **5**ss (2 grammes);
- Styraeae, .......... **m**v (0.3 gramme);
- Olei eucalypti, .......... **5**i (25 grammes);
- Petrolatii, .......... **5**i (12 grammes);
- Calcii carbonatis, .......... **5**ss (90 grammes);
- M. ft. unguentum.
NEW YORK MEDICAL JOURNAL

INTRATHORACIC INJECTIONS OF IODINE
IN TUBERCULOSIS.

As emphasized by Cavazzani last year, iodine has held its own in the treatment of tuberculosis, and is a potent aid in the sanatorium treatment of the pulmonary form. But it must be given in moderate doses, lest, as demonstrated by Capelli, it depress phagocytosis, a process enhanced by appropriate doses. Moreover, large doses evoke an excessive and depressing general reaction. Iodine and the iodides have been used advantageously by the mouth, and, where this mode of administration tended to cause gastric disturbances, hypodermically. The beneficial effects of iodine are doubtless due to the bactericidal properties, partly direct and partly phagocytic, with which it is endowed, as emphasized by the observations of Grossich, Réclus, Walther, Woodbury (see our issue of February 11, 1911), and others. This applies for the results obtained recently by d'Amico in a series of twenty-two cases of pulmonary tuberculosis treated by means of intrathoracic injections of iodized fluids, the aim of the Italian clinician being to bring the iodine into contact with the diseased pulmonary foci, whether a cavity or an area of tuberculous infiltration. Although the cases were more or less advanced, and other methods had afforded but little encouragement, very distinct amelioration of their condition was obtained. The injections were well borne, no hemorrhage was caused, even where hemoptysis had previously occurred. Two of the patients were children aged four and ten years, respectively. The solution preferred by d'Amico (Lancet, March 29, 1913) consisted of iodoform, one gramme (fifteen grains); camphor, two grammes (thirty grains); guaiacol, five grammes (seventy-five grains); essence of peppermint, thirty drops—a quantity we deem excessive and needlessly irritating—and olive oil, twenty grammes (five drachms). The needle, preferably of platinoridium, should be of fine calibre and from three to five cm. long. In adults from twenty to sixty injections were administered, according to the extent of the disease, while in the two cases in children, ten sufficed. One cubic centimetre (sixteen minims) was the amount usually injected, but as much as from four to six c. c. (one to one and a half drachms) was required for cavities. Avoiding the cardiac area and large vessels while introducing the needle into the appropriate intercostal space, the solution is injected directly into the affected pulmonary area. The most favorable region is that comprised between the second and sixth ribs on either side. The apex is best reached through the dorsoscapular intercostal space.

Of the tuberculous nature of the cases treated there could be no doubt. The injections caused disappearance of the tubercle bacilli from the sputum, gradual cessation of the fever and cough, all other physical signs being also gradually eliminated. Open air exercise and the patients' daily avocations being in no wise interfered with, they progressed steadily toward recovery while earning their livelihood—a matter of vast importance when we realize that the majority of cases occur among those most exposed to infection, the working classes of our great cities.

THE SMOKE NUISANCE AND PERNICIous COURT DECISIONS.

Without going very deeply into the merits of the law involved in the recent nullification, by a decision of a lower court in New York, of the ordinance passed by the New York Board of Health in relation to the smoke nuisance, it is clear that sanitary progress has received a great setback, at least temporarily, it is to be hoped, through this decision. The court has taken upon itself the burden of deciding that a general ordinance against the emission of dense smoke was an unreasonable exercise of the police power of the State. The court seemed to think that the restriction of an industry was of more moment than this question of the public health, though it is plain that the restriction consisted only
in the expenditure of a little more money in the use of hard coal as a fuel, to say nothing of the extravagance entailed in the use of oil as a fuel, as is now done in many industries.

And yet this city is rather fortunate in having a separately incorporated health department, chartered directly by the State and independent of any other body in the promulgation of its ordinances. Its rulings have the force of legislative acts. This mode of health administration constitutes the highest form of progress in the sanitary control of the community. It takes out of the hands of the uninstructed the matter of health and places it into the hands of those fitted by training and experience to administer such matters. But the reasonableness and the justice of these ordinances and, as is also the case with the acts of the legislative bodies, is reviewable by the courts. This may appear to the lay mind as a just check on the health authorities, but this case shows that it is not safe to leave to the lay mind the final determination in matters of the public health.

From the very nature of their work health authorities meet with a great deal of opposition. They are constantly interfering with liberty or property in carrying out their mission. But to accomplish any results health officers must be given wide latitude and their discretion and judgment must be taken in absolute good faith. A learned court remarked on this subject: "A health officer, who is expected to accomplish any results, must necessarily possess large powers and be endowed with the right to take summary action, which at times must trench closely upon despotic power." Whether the emission of dense smoke is detrimental to the public health is surely a question for sanitaritians. The criterion of the validity of a health measure is only whether the public in its aggregate will be benefitted. The beneficial effects on a community of a clear unclouded sky, and an unirritating atmosphere cannot be overestimated, nor can the depressing effect of a smoky, murky atmosphere be ignored. In respect to the character of the atmosphere New York city is almost a city by itself. The health department is to be given the largest part of the credit for the reputation this city bears of being one of the best health resorts.

The mere fact that an industry, whose operation tends to create a nuisance, was first established in an uninhabited district, and possibly to avoid this very result, but later a habitation grew around it, to whose inhabitants the operation of that industry was detrimental, is now held to be no defense against its removal from amidst this habitation.

This decision is a decided retrogression, when it is considered that the tendency almost universally is to regard a measure justly within the police power of the State and, therefore, to be sufficient justification to take property or even liberty "without due process of law," when not only the health, welfare, and safety of the community is involved, but even its mere convenience. It is to be hoped that the higher tribunals will see the menace to public health progress in thus putting at nought the judgment of the health board.

FRESH AIR AS AN ELIMINATOR OF THE EXANTHEMATIA.

In no other condition is the beneficial effect of fresh air more strikingly shown than in the case of the exanthemata. In tropical countries, where the people divide their time between the open air and houses so constructed that the outside air has at all times the most complete access to all parts of them, these diseases are practically unknown; and if, in New York, we were to have all the year round the conditions which now prevail during the summer months, there can be little question that they would disappear here.

These remarks have been suggested by the recent announcement made by the health department that in one of the weeks of July, for the first time in many years, not a single death in the city was reported from scarlet fever. Such an absence of mortality, indicating, naturally, a very small incidence of the disease, could have occurred, it may safely be asserted, only in the summer season or early autumn. The whole story of the exanthemata in New York and elsewhere in this part of the world was given in a nutshell, so to speak, some years ago, when Doctor Blauvelt, of the health department, tersely remarked: "Measles and scarlet fever appear every year as soon as people close their windows and keep out the fresh air."

This statement, of course, needs some qualification, as these diseases never entirely disappear, since, in the few months intervening between the recession and advance of cold weather—the period of open windows—there is not time enough for them to become eradicated. A striking illustration of the injurious results of a lack of fresh air in the presence of infectious disease is shown in the case of smallpox in Russia. In that country, as is well known, this disease is still very prevalent, owing, no doubt, primarily to inadequate vaccination among the inhabitants, but very largely to domiciliary conditions; it is said to be attended by a frightful mortality. On account of the intense cold of the long winter, the people keep themselves
shut up as much as possible in their houses, where a high temperature is maintained and everything done to exclude the outside air. Under such circumstances a contagium becomes very concentrated and the results are most disastrous. Formerly, when a number of typhus patients were treated together in hospital wards, the condition was such that a very brief exposure to the atmosphere of a ward was usually sufficient to impart the disease to a perfectly healthy individual. Later, however, when the cases of typhus were treated in tents out in the open, it was found that the poison, largely diluted with fresh air, quickly lost its potency.

The health department records show that the mortality from measles and scarlet fever gradually increases as the weather grows colder in the late autumn. During the winter months there is naturally more or less variation, but the maximum death rate is not usually reached until some time in the spring.

As to any method of contending successfully against these diseases, other than the use of the measures already employed to prevent their spread, the only hope, of course, is the somewhat chimerical one of so educating the people that they will have some appreciation of the real facts of the case. During the past school year an encouraging experiment was made in one of the public schools of Philadelphia. In one of the rooms the windows were kept constantly open, and at the end of the year it was found that the children of this room were in every way in better condition than the children of the same age and class, in a room of corresponding character with ordinary ventilation and in which the windows were for the most part kept closed.

AUTOGÈNEUS VACCINE IN TYPHOID FEVER.

According to Presse médicale for July 23, 1913, Josué and Belloir, at a recent meeting of the Société médicale des Hôpitaux of Paris, reported that they had treated twelve cases of typhoid fever by auto-vaccination. Their method is as follows: As soon as an individual suspected of having typhoid fever is admitted, blood cultures are made, which usually become positive at the expiration of forty-eight hours. The last culture is then sterilized by heat (56° C.) for six hours and, after estimating the number of bacilli contained in one c. c., the authors begin vaccinating the patient, injecting three successive doses, each of 200 million bacilli, at intervals of twelve hours. If, after five days, the temperature remains above 38° C. an additional injection of the same number of bacilli is administered. This in most instances results in the rapid improvement of the patient. Severe cases of typhoid run, after vac-

Doctor Ladinski, in the American Journal of Obstetrics and Diseases of Women and Children for August, 1913, comments on the lack of definite signs or symptoms indicating an early stage of pregnancy and then calls attention to what he considers a positive sign. To quote his words: “The change I have invariably found in early uterine pregnancy consists of a circular area situated in the median line of the anterior surface of the body of the uterus just above the junction of the body and cervix, that is to say the isthmus of the uterus, which varies in size according to the duration of pregnancy, and offers to the palpating finger the distinct sensation of elastic fluctuation. It can frequently be made out as early as the fifth week, when the area is only the size of a finger tip; but it can always be felt in the sixth week, when it is somewhat larger. As pregnancy advances this area increases in size in a crescentic manner, and extends upwards toward the fundus until the third month of pregnancy, when nearly the entire anterior body of the uterus presents a fluctuating, cystic feeling to the examining finger.

MEDICAL ASPECTS OF GOITRE.

I. V. Lemann, in the Interstate Medical Journal of August, 1913, states that the new kinetic theory of Crie is very attractive to the medical man because it justifies his statement that most patients will be benefited by nonsurgical measures. Whether this theory is adopted or not, all must agree that the most important point in treatment is rest—rest in bed—until all symptoms have disappeared. Hydrotherapy is invaluable, warm baths, cold applications to the enlarged thyroid, ice bag to the heart for palpitation. In the way of drugs, tonics such as quinine, iron, and arsenic—quinine hydrobromate has seemed to act almost as a specific. Digitalis and its congeners, for the regulation of the heart, are to be used just as in other heart conditions, and the bromides are useful in quieting nervousness. If we look upon Graves’s disease as hyperthyroidism, certainly iodine and all thyroid preparations are to be interdicted. and even if one is inclined to other theories, must be employed with great caution. More logical, from the standpoint of hyperthyroidism, is the use of organic preparations from thyroidectomized animals With these, as with the Rogers and Beebe serum the author’s experience is small.
Obituary.

AUGUSTUS MAVERICK, M. D.,
of San Antonio, Texas.

Doctor Maverick was killed almost instantly on August 18, 1913, while defending a cook employed in the doctor's family against the attacks of a lusty mad negro. The murderer had already severely wounded the girl, and after killing the doctor attacked one of the daughters of the physician, when he in turn was seriously wounded by the aged father of the murdered man. In less than five days after the crime, the assailant was tried and convicted. The trial had lasted not quite two days. The date of execution will be set during this month.

Doctor Maverick was a well known practitioner of San Antonio, his native town. Born on November 12, 1853, he received his medical education at the University of Pennsylvania, from which he was graduated in 1877. After a postgraduate course in Vienna, he returned to his native town, where he had practised since. He was well known in medical circles. a good writer on medical subjects, and an esteemed contributor to the Journal. A widow and two children, six and four years of age, survive him.

News Items.

Conference on Pellagra.—Dr. Louis W. Sambon, of the London School of Tropical Medicine, delivered an address at the conference on pellagra held in Spartanburg, S. C., on Friday, August 29th.

Vermont State Medical Society.—This society will celebrate its one hundredth anniversary at the annual meeting to be held in Burlington on October 8th, 9th, and 10th, under the presidency of Dr. B. H. Stone, of Burlington. The local committee in charge of arrangements is composed of Dr. C. A. Pease, Dr. E. T. Brown, and Dr. F. J. Arnold. Every effort is being put forth to make the meeting the best in the history of the organization.

Harvard Expedition for Study of Tropical Diseases.—Dr. Richard P. Strong, professor of tropical diseases at Harvard University, Ernest E. Tyzzer, assistant professor of pathology and director of the Cancer Research Commission at Harvard, and Dr. C. T. Brues, of the Bussey Institute, who left for South America on April 30th last, for the purpose of studying tropical diseases in that country, have returned home. Three weeks were spent in Guayaquil, Ecuador, but most of the time was devoted to investigating the cause of a contagious disease, prevalent in Peru, called "verruca peruana." The expedition was financed by the department of tropic medicine of Harvard University, and is said to have been highly satisfactory from a medical point of view. An interesting report will soon be presented to Harvard University.

Library of Radiographs.—An attempt is being made to establish, at the Army Medical Museum, Washington, D. C., an extensive library of lantern and stereoscopic slides of radiographs, representing the work of radiographers who have done particularly notable work along certain lines. So far, only a small number of slides have been received to make the collection of value for reference and for teaching purposes at the Army Medical School. Those who have already contributed to the collection are Dr. Lewis Gregory Coast, of New York, slides of stomach, lungs, and kidneys; Dr. William H. Diemben, of New York, slides of diseases of bone; Dr. Kennon Dunham, of Cincinnati, stereoscopic slides of the lungs; Dr. Walter C. Hill, of Cleveland, slides of diseases of bone; and Dr. James T. Case, of Battle Creek, Mich., slides of the alimentary tract. Others have promised to send slides, and the intention is to add to the collection from time to time as important work is done. The collection is available for study by any civilian practitioner on application to the Curator, Army Medical Museum, Washington, D. C.

New Officers of American Federation of Sex Hygiene.—At a meeting of this organization, which was held in Boston last week in connection with the Fourth International Congress of School Hygiene, the following officers were elected: President, Dr. Charles W. Eliot, president emeritus of Harvard University; vice-presidents, Dr. David Starr Jordan, of Leland Stanford University; William Foster, of the University of Chicago; Dr. E. W. Webster, of New York, and W. T. Sumner, of Chicago; secretary, Dr. Donald R. Hooker, of Baltimore; treasurer, Henry L. Higgison, of Boston.

American Hospital Association.—At the annual meeting of this association, held in Boston on August 27th, 28th, and 29th, under the presidency of Dr. Frederick A. Washburn, head of the Massachusetts General Hospital, the following officers were elected to serve for the ensuing year: Dr. Thomas Howell, superintendent of the New York Hospital; president; Dr. H. E. Webster, of the Royal Victoria Hospital, Montreal, first vice-president; Miss Mary A. Baker, superintendent of St. Luke's Hospital, Jacksonville, Fla., second vice-president; H. J. Boro, of Kingston, Ont., secretary; and J. Austin, of the Presbyterian Hospital, Chicago, treasurer. Next year's meeting will be held in Baltimore.

Changes in the Staff of the University of Alabama.—Dr. Andrew H. Ryan, instructor in physiology and pharmacology in the University of Alabama, was appointed chairman of the department of pharmacology in the University of Alabama, succeeding Dr. John Van de Evere, who resigned recently to accept a position in Marquette University, Milwaukee. Other appointments of the department of the University of Alabama are the following: Dr. Howard H. Bell, of the University of Pennsylvania, full time assistant in the department of pathology; Dr. Jesse P. Chapman, instructor in orthopedic surgery; Dr. Percy J. Howard, associate professor of surgery; Dr. E. S. Sledge, instructor in radiography; and Mr. Julius G. Henry, instructor in medicine.

Old Battleships as Tuberculosis Sanatoria and Open Air Schools.—At the Fourth International Congress on Tuberculosis, held in Guayaquil, Ecuador, last week, Dr. Adolphus Knopf, of New York, presented a resolution, which was adopted unanimously, endorsing the proposal to ask the United States Government to convert one of the discarded battleships and cruisers into tuberculosis sanatoria and open air schools, and also for the establishment of open air schools. The resolution states that there are nearly one million tuberculous children in the public schools of the United States, and that the country could provide accommodation for fifteen hundred. Italy has already adopted the plan, and the resolution included a vote of appreciation of this action on the part of the Italian government.

World Federation.—Dr. Wade H. Brown, professor of pathology in the University of North Carolina, has resigned, to accept a position on the staff of the Rockefeller Institute for Medical Research, New York. Doctor Brown's successor will be Dr. James A. Bullitt, late of the University of Mississippi.

Doctor Roux, director of the Pasteur Institute, Paris, has been appointed a grand officer of the Legion of Honor. Dr. A. Bachmeister and Dr. L. Küpferle, of Freiburg, Germany, have received $5,000 from the Robert Koch Foundation, for their studies in Röntgen therapy in tuberculosis.

Dr. Calvert M. De Forest, who recently returned from Liban, Russia, where he represented the United States Public Health Service for five years, has been appointed deputy health officer of the port of New York.

Mr. George C. Signor, for eight years superintendent of the Medico-Chirurgical Hospital, Philadelphia, has resigned, to take charge of the administration of the Feebodied and Epileptics, at Spring City. He assumed his new duties on August 29th.

Dr. Mary W. Griscom, of Philadelphia, sailed on September 2d from New York for Japan. It is her intention to spend three years in the Far East.

Dr. Louise Pearce, a member of the staff of Johns Hopkins Hospital, Baltimore, has been appointed an assistant to Dr. Simon Flexner, at the Rockefeller Institute for Medical Research. It is said that this is the first time a woman has been appointed to engage in research work in that institution.
Death Rate in New York.—During the week ending August 30, 1913, there were reported 1,271 deaths from all causes, corresponding to an annual death rate of 12.37 in a thousand of population, as compared with a rate of 12.26 for the corresponding period in 1912. The diseases which showed increased mortality last week were measles, diphtheria, croup, and whooping cough. There were forty-six fewer deaths of children under one year of age than there were the last week of August, 1912.

Tuberculosis Day.—Sunday, December 7th, has been designated this year by the National Association for the Study and Prevention of Tuberculosis as the fourth national Tuberculosis Day, and as such will be observed by churches, schools, labor unions, fraternal orders, and other organizations in all parts of the country. The movement will be furthered by about one thousand and one hundred antituberculosis societies working through various State organizations and the national association. Personal appeals will be made to clergymen, school principals, and leaders of organizations urging them to set aside a definite time on or about December 7th for a lecture on tuberculosis.

Gifts and Bequests to Hospitals.—The will of Mrs. Julia Lorillard Butterfield, who died recently at Cold Spring, N. Y., devises that a hospital is to be erected at some spot accessible to both Cold Spring and Nellsville, Putnam County, N. Y., to be known as the Julia L. Butterfield Hospital. $100,000 is given for the construction of the building, $10,000 for its equipment, and $100,000 left in trust for its maintenance. The will also contains a bequest of $20,000 to the Association for the Relief of Respectable, Aged, Indigent Females, at 104th Street and Amsterdam Avenue, New York, and a bequest of $2,000 to the Association for the Relief of Crippled Children.

Many organizations of a charitable nature are beneficiaries under the will of Mrs. Clarence C. Hardy, who died in Newark, N. J., on July 20th. The Young Women's Christian Association receives $5,000 outright, while to St. Barnabas Hospital and the Home for the Friendless are each given a trust fund of $5,000 for the maintenance of beds in these institutions. After noting several bequests to individuals, the will directs that the residue of the estate be divided equally between the Hospital for Women and Children and the Home for Crippled Children. The amount which will be divided between the residuary legatees is believed to be large, although no accurate estimate is as yet available.

A School for Health Officers.—Beginning this fall, Harvard University and the Massachusetts Institute of Technology are to maintain in cooperation a school for public health officers. The facilities of both institutions are to be available to students in the school, and the Certificate of Public Health (C. P. H.) is to be signed by both Professors N. P. Lowell and President Macdowell. The object of this school is to prepare young men for public health work, especially to fit them to occupy administrative and executive positions, such as health officers or members of boards of health, as well as secretaries, agents, and inspectors of health organizations. It is recognized that the requirements for public health service are broad and complicated, and that the country needs leaders in every community, fitted to guide and instruct the people on all questions relating to the public health. The instruction of the new school will be on the broadest lines. It will be given by lectures, laboratory work, and other forms of instruction offered by both institutions, and also by special instructors from national, State, and local health agencies. The requirements for admission are such that graduates of colleges, or technical and scientific schools, who have received, adequate instruction in physics, chemistry, biology, and French or German, may be admitted to the school. The medical degree is not in any way a prerequisite for admission. Although the administrative board strongly urges men who intend to specialize in public health work to take the degree of M. D. before they become members of the school for health officers. The administrative board, which will conduct the new school, is composed of Professors William T. Sedgwick, of the Massachusetts Institute of Technology, Dr. Milton J. Rosenau, professor of preventive medicine and hygiene, Harvard University, and Professor George C. Whipple, of Harvard University. Professor Rosenau has the title of director, and the work of the school will be under his immediate supervision.

Diet in Diseases of the Heart and Blood-vessels.—H. Vaquez states that the regular and moderate use of alcohol is not always the only cause of increased blood pressure, but simply one among others. It is nevertheless not a cause of which cannot otherwise be explained. In patients with cardiac insufficiency and a contracted kidney, the total amount of fluids is also reduced. The disturbances caused by the abundance of fluid at this time are vomiting, dyspnea, at times menacing edema of the lungs and frequently increased blood pressure. When cardiac insufficiency and lesion of the kidneys coexist, food and drink must be still more limited, and the limitation should cover a longer period of time. A salt free diet is advocated. The drinking of milk should be restricted to within two litres during the day, because its contents albumin is apt to produce acetoneuria, which is especially to be avoided. All excess of meats is to be avoided and drink should be used sparingly at and infrequent intervals. It is therefore necessary to adhere to vegetables and fruits. This diet contains much less nourishment. On the whole the character of the diet should be governed by the excretions. The patient is to be restricted in those articles of the dietary which the diseased organs cannot excrete. The attentive study of clinical facts and laboratory examinations should be the physician's guide, rather than empiricism.

Noviform in Rhinology.—G. Dinolte states that noviform advantageously replaces iodiform. While it has all the advantages of iodiform, it possesses none of the objectionable features. The author has had very good results with noviform gauze and an emulsion of noviform petrolatum. It is nonirritating, hygroscopic, and nonpoisonous, as well as nonodoriferous.

Vomiting of Pregnancy.—R. Asch explains that vomiting in itself is not a disease but a symptom. It is seen in fear, pain, sorrow, or feeling of dislike. Excitation of the sensory nerves by the sight of food stimulates the digestive secretions, which are at once inhibited by the sight of anything unpleasant or disgusting or any feeling of dislike. Women or girls at times become pregnant against their wishes. The resulting vomiting becomes a habit. The pernicious form of hyperemesis develops at times from these causes and from the lack of proper instruction. The disproportion between the subjective sensations and the necessity for food explains the cause of disturbance. Small meals every two and one half hours, solid and fluid meals alternating, should be taken in the reclining posture: the patient lying down for some time after. The author also advises larger meals to be taken while lying down. No fluids at the same time with solids, but each should be taken separately. With one very sick patient the writer
had good results after giving the fluid nourishment and drinks frozen in the form of frappés for fourteen days. Frozen milk, milk coffee, milk tea, water cocoa, apple sauce, and fruit ices. The patient was kept on these frozen fluids until she asked for beefsteak, which she ate with relish and retained from that time. The psychic treatment may consist in properly teaching the patient that pregnancy is not a disease, and childbirth is not a dangerous process; also warn her against the inquisitiveness and advice of those in her environment.

Experience with Hexal.—E. Bäumer states that among the numerous urinary antiseptics of today, hexamethylentetramine has still first rank. The author mentions along with its good points at least two of its ill effects. It increases any existing strangury, and at times increased the inflammation of the urinary mucosa, which is expressed by a burning sensation or even hemorrhage. Facts and observations show clearly that both components of hexal, sulfosalicylic acid and hexamethylentetramine in combination heightens the sedative and astringent action of the sulfosalicylic acid over and lessens the irritating effect of hexamethylentetramine. Hexal is in fact what it was proposed to be, a sedative bladder antiseptic. The greatest advantages of hexal tablets are their solubility in water and their pleasant acid taste. Of forty patients, treated with hexal, mostly with gonorrheal infection of the urinary tract, only two or three, who were very severely ill, required additional remedies. The general dose is three tablets daily, according to the severity of the disease. On increasing the dose its good effects are immediately increased. No cumulative action need be feared.

July 21, 1913.

Mesotherium for Gout and Nonacute Rheumatic Affections.—Görges describes the mesotherium compresses as follows: They consist of asbestos fibres, which have the active salts incorporated, in insoluble form. This compress is wrapped in a covering of English lint. The intensity of action varies according to size. In a compress of 20 x 30 cm. there is the relatively large quantity of one to two milligrammes of mesother salts and radio bromide strength. The compress is moistened with physiological salt solution warmed to 08.5° F. It is made pliable to conform to the painful parts and joints, and covered with Billroth's taffeta is fastened with a flannel bandage. The application is left on from one to twelve hours. It produces absolutely no ill effects on the skin or organs. Inhalations are made three times weekly, each of three minutes duration. The excretion of uric acid is increased under the influence of radium emanations. Thorium emanations act in like manner; so much so, that after inhalation, the increase in the relative quantity of uric acid excreted daily is very apparent, although the purin content of the diet is kept the same during the time of the inhalation treatment.

Adiposis Dolorosa.—Kloninger observes in these patients a painful fat proliferation, a feeling of general infirmity, and a mental change, mostly of a depressing nature, all apparently without any organic changes. The disease is found more among females and often occurs after changes in the reproductive organs, as childbirth, abortion, menopause, ovariectomy. Nothing certain is known of its etiology, although it is supposed to be caused by the influence of diseased glands through their altered internal secretion. At autopsies changes were found partly in the thyroid, pituitary body, also in the ovary, testicle, and suprarenal capsule. Most often the thyroid gland was found affected (atrophied, colloid degeneration, diffuse cirrhosis). The author presents a photograph of one of his patients whom he treated as follows: Thyroid tablets three times daily, each 0.1 gramme. These are generally well tolerated by the patients. Hydro-therapeutic treatment was given to increase the metabolism. Headache was favorably influenced by the high frequency current. After four months of treatment a marked, general improvement was noted; pains were less; the patient, who had been bedridden, was able to attend to her household duties and was not at all excitable. When all pain had ceased general effleurage was resorted to with good results.

July 28, 1913.

Operative Cure of a Tumor of the Gasserian Ganglion.—B. Sachs and A. A. Berg report this case, not only on account of the successful issue, but because tumors of the Gasserian ganglion are very rare, and the diagnostic difficulties were of an unusual nature. The patient was an unmarried man of thirty-seven years; family history good; moderate in the use of tobacco and alcohol; no history of venereal infection. Pains began with a burning sensation in the left side of pharynx, also anterior to the left ear and in the left cheek. Long continued pains, having the same characteristics, are generally of organic origin; but it is rare, as in this patient, to find a double origin for the one ailment; so it may easily be imagined, that in the face of an affection of the antrum, from which was removed several ounces of thick, white pus containing staphylococci, the authors were nonplussed to find that after evacuating the antral abscess cavity the pains had not in the least been relieved. Even after successful cleansing and later removing some remaining necrosed spicules of bone, the pains became even worse. It was not until the motor branch of the fifth nerve became involved and the present rapid increase of the patient's sufferings, directed attention to a tumor of the Gasserian ganglion. The pressure symptoms, absent from the beginning to the end, increased the difficulty of diagnosing this other origin of the disease. The tumor which was successfully removed proved to be of endothelial nature, probably originated in the dura and entirely enveloped the ganglion. The excellent condition of the patient the day after operation was most striking, and the uneventful convalescence is ascribed to the careful manipulations on the brain, and above all to the slight amount of bleeding.

CORRESPONDENZBLATT FÜR SCHWEIZER ÄRZTE.

July 26, 1913.

The Behavior of Leucocytes in Great Altitudes.—Wanner has made a study of the blood corpuscles of persons coming into the mountains and finds a
great increase of the red blood cells and a decrease of the leucocytes at various periods ranging from two weeks to five months. He also finds that there is a diminution of the neutrophil polymuclear cells, with a great increase of the large mononuclear and of the transition forms. He therefore believes that a great altitude affects the ability of the bone medulla as a whole in the production of both the white and the red corpuscles.

**MUNCHENER MEDIZINISCHE WOCHENSCHRIFT.**

_July 1, 1913._

**Differentiating Related Bacteria in the Precipitating of Their Albumins by Concentrated Solutions of Salts.**—H. Liebmann describes this method for the detection of pathological conditions of the cerebrospinal system. It consists in taking a certain quantity of fluid by lumbar puncture mixed with the same quantity of a concentrated solution of ammonium sulphate. The author tested several varieties of bacteria and found that by using different degrees of concentration, even the very closely related bacteria could be differentiated. Albumin precipitates do not influence the suspension of different bacteria in the same degree. Of the light metals ammonium sulphate was first used as a precipitant; but for differentiating closely related germs it is not as useful as magnesium sulphate.

**A Simple Aid to Replace a Protruding Hernia in the Infant.**—A. Nussbaum observed that blowing in the face of crying infants causes them to be quiet at once. The author made use of this expedient in connection with a little patient of three months, who had been suffering with an irreducible hernia for nine hours. It was situated in the right inguinal region and contained a portion of the intestines the size of a plum. The infant was placed with the buttocks slightly elevated, and while forcible puffs were blown into its face by the operator, the child stopped crying, the abdomen became relaxed, though he struggled with hands and feet while held. The blowing was kept up while the hernia was slowly but steadily being replaced by taxis, and retained in position by a band of adhesive plaster, which prevented any relapse. This method of blowing may also be utilized to facilitate palpation of the abdomen in crying infants.

**Pituitrin Treatment.**—Grunmain relates his experience with pituitrin given during the first stage of labor as follows: While the remedy excited the musculature of the uterus, it caused a prolonged contraction on a rigid cervix which led to untoward complications. The prolonged contraction due to pituitrin differed greatly from the physiological normal labor pains. The coming and going of the pains and not the contraction itself causes the dilatation of the birth canal and the expulsion of the child. The author advises caution in the use of pituitrin during the stage of dilatation. He prefers to wait.

_July 8, 1913._

**Iodostarin.**—G. Stumpke states that the ill effects of iodism rarely appears with iodostarin. The author has continued the use of the remedy in cases of corvza and intestinal disturbances, without untoward effects. He also noted that iodostarin was well borne by those who formerly could never take any preparation of iodine without showing signs of iodism. Two or three tablets taken during the day are used to begin with, and may be increased to six tablets daily. The author has had gratifying results from this remedy in patients suffering with tubercle. It has a pleasant taste, and has found a special place in the treatment of lues, especially in the second stage, for the headache, bone pains, and meningial irritation; in tertiary processes where the usual antituberculous treatment does not prove satisfactory, the author finds this remedy useful.

**Treatment of Pyelitis by Irrigating the Pelvis of the Kidneys.**—H. Holzherr presents the following: For irrigations one half to one per cent. solution of nitrate of silver was used. The idiosyncrasy of patients to the nitrate of silver varied greatly; sometimes after treatment the urine contained albumin, an increase of leucocytes, and at times blood. In these patients the author substituted collargol, but even with this the irrigations were not always painless. Two or three irrigations were given weekly. At times the writer used from five to ten per cent. solutions of argyrol. With the use of these solutions pain was never experienced; but the price of the argyrol would forbid its general use. Hartmann has had good results in a large and varied experience with perhydrol, where no pain at all was experienced; this remedy is as good a germicide as nitrate of silver. Those that favor this treatment believe that not only a clinical but also a bacteriological healing process is accomplished by this method, which has proved itself more efficient than all others heretofore used. The disease should be detected and treated early. The earlier the treatment is adopted the more quickly and certainly is healing accomplished.

**The Tendency of Colipylitis to Spread.**—F. Mayer says that pregnancy is usually attributed as a cause to existing pyelitis at that time. As a result of his large experience with pyelitis in men, the author states that pregnancy instead of being a cause of pyelitis, only predisposes one to that disease. Most authors mention only an ascending infection, but according to clinical symptoms there is also a descending infection of the pelvis of the kidneys by way of the blood and lymph channels, as evidenced after infectious diseases. The writer also tells of the ease with which hemorrhage resulting from pyelitis may be mistaken during pregnancy as being of uterine origin. In one of his patients the bleeding was so profuse as to simulate a hemorrhage from a placenta previa. This interesting clinical picture of pyelitis suggests many significant references to pregnancy.

_July 15, 1913._

**Exchange of Foodstuffs in Parabiosis.**—B. Morpergo and G. Satta have shown that a young parabiotic rat may live and grow, fed exclusively on saccharose, while her partner has a nonnitrigenous mixed diet. This fact does not depend upon the food being evenly divided between both partners because in depriving the sugar rat of her sugar she promptly died of acute inanition. As a result of this it may be concluded that the parabiotic rats exchange nitrigenous foods but no continuous mixing of nutritive fluids takes place; because to fill the caloric requirements the immediate passing in of
energy producing materials at once takes place. The authors can give no exact information with regard to the quantity of nitrogenous substances passing from one to the other; but they do know that it must be very small because of the length of life and the loss of weight of the hungry parabiose animals is not different from that of other single animals in a state of starvation. In consequence of this a new basis is offered in place of the former rules for keeping the body of the organism in good condition. The quantity of nitrogenous food-stuff required for a growing organism is, by far, less than that which has formerly been believed necessary for the purposes of metabolism.

Paroxysmal Tachycardia.—K. Grassmann states that from his observations on fifteen patients, some extending over many years, attacks of tachycardia covering a period of a week, lead to dilatation of the heart with all the severe symptoms accompanying that condition, because the heart muscle has simply exhausted itself from overfatigue and its function is impaired or possibly destroyed. Gerhardt says that paroxysmal tachycardia is a neurosis, the nature of which is not yet fully understood. It is due to abnormal excitation, and is not the result of any organic change. The cause may be, for instance, fright or simply-stooping. Hoffmann groups the following as causes: Heredity, nervous diseases, accidents, alcohol, nicotine and anemia.

Treatment of Hordeolum and Blepharitis Ciliaris with Histopin.—R. Vollert states that histopin therapy is effectual against staphylococcus infection of the skin, especially of the external skin of the eyelids. The author substantiates this with a report of eighty patients treated with amazingly prompt recovery. The treatment consists in the application of histopin ointment, after opening any pustules that may be present. The histopin ointment is stroked on the lids for eight or ten days after apparent healing as a prophylactic. Joseph observed along with favorable results some not as effectual, but these cases were invariably proved to be due to a streptococcus infection. To prevent relapses Marenholz would warn against such causative factors as neglected refractive errors, strabismus, digestive disturbances, constipation, compression of the throat as by collars, tight lacing, narrow shoes, wetting the hair when brushing or combing it; any of these may make the ailment worse.

Inverse Action of Atropine.—Rudolf Kaufmann and Hedwig Donath report a case met with in a man forty-one years old in whom the injection of atropine produced an unusual result. The pulse of the patient showed spontaneously great fluctuations in rapidity. Repeated examinations after the injection of atropine showed first a slowing of the frequency of the heart beat, which in about twenty minutes passed into an acceleration; as soon as the auricular pulsation reached a height of about 90, partial or total heart block supervened, so that during the course of each observation there was seen first a true slowing of the pulse, then an acceleration of the same, and then an apparent slowing with arrhythmia.

Radium Treatment of Malignant Tumors.—Alfred Exner asserts that he can dilate stenoses of the esophagus due to carcinoma by means of radium, as shown by the results on twenty patients. Perforation occurred in two of these; in one into the trachea, in the other into the mediastinum; possibly this perforation would not have occurred at all, or would have taken place later, had it not been for the radium treatment. Of forty cases of deep seated cancer elsewhere on the body, recurrence appeared in all but two within three years. One of the patients with a carcinoma of the mucous membrane of the mouth died from recurrence nine years later, the other case, a carcinoma of the upper lip, recurred after seven years.

Adipositas Hypophysarea.—Theodor Bauer and Hans Wassing state that certain trophic and metabolic disturbances, even when not accompanied by symptoms that indicate a tumor in the pituitary gland, must arouse suspicion of an affection of the hypophysis when the thyroid gland is felt.

Empyema Pulsans Interlobare.—Ettore Levi describes a case of empyema in a boy seventeen years old, over whose back and side and in the axilla could be felt a diffuse pulsatory impulse of the entire wall of the thorax, best marked in the upper intercostal spaces, corresponding to the interlobar space.

ZENTRALBLATT FÜR CHIRURGIE.

The Use of Spring Retractors in the Treatment of Suppurative Processes.—Max Tiegel has devised a little retractor, resembling somewhat an eye speculum, which he inserts between the lips of an incision into an abscess and leaves in position for some hours. This allows the pus to escape freely and shortens the period of healing.

LYON MÉDICAL.

Coexisting Ileoceleal and Pulmonary Tuberculosis.—Santy and Durand report a case in which hypertrophic tuberculosis of the ceum was diagnosed and operative treatment undertaken, in spite of the fact that the patient was suffering from active lung disease, was cachectic and emaciated, and so enfeebled as to be almost constantly confined to bed. The ceum, ascending colon, hepatic flexure, and the terminal part of the ileum were removed, and the hypertrophied ileum anastomosed end to end with the transverse colon. The abdominal pain and digestive disturbances were thereby relieved, permitting increased alimentation and the administration of arsenic. Rapid improvement in the general and pulmonary conditions followed. Sodium arsenate was at first given, but later a series of eight rectal injections of salvarsan. Coincidently with the latter the agglutinating power of the blood was observed to increase and fever to disappear. The chief interest of the case lies in that it showed excision of the diseased bowel to be permissible even at a relatively advanced stage of pulmonary tuberculosis and where the lung condition was primary.
Electric Treatment of Trifacial Neuralgia.—E. Albert Weil recommends the trial of strong galvanic currents before resorting to operation in this disorder. The necessary apparatus comprises a battery of twenty-four, or better, thirty-six cells, with a milliamperemètrement and rheostat. The whole neuralgic area is covered with an electrode consisting of twelve to fifteen thicknesses of gauze moistened with saline solution, and held in close contact with the head by tight bandages. The other (negative) electrode is applied to the back of the patient, who is kept recumbent during the treatment. The current is increased in three to five minutes from nil to eighty milliamperes, the latter being then continued for from thirty to forty minutes. At the end of the séance the reduction of the current to zero should likewise be gradual. Daily sittings generally suffice, and improvement is usually manifest after the fifth or sixth treatment. In case of failure, ionic medication, the facial electrode—now to be connected with the negative pole—being moistened with a one per cent. solution of sodium salicylate, should be tried before abandoning the procedure.

Relations of Inferior Vena Cava to Pelvic Organs.—M. Bourcart shows that descent of the right kidney or the liver, as well as all changes in volume of the latter organ, tend to produce torsion of the inferior cava and hence favor congestion of the pelvic organs. In the treatment of uterine hemorrhage, principally certain post partum hemorrhages, hemorrages at the menopause, and hemorrhages in cases of uterine fibroma, as well as in congestive metritis, and ovarian circulatory conditions reacting on the uterus, much can be done by massage of the abdomen. This massage should comprise such manipulations as pushing the mass of intestines toward the diaphragm, separating the false ribs, executing manual vibrations below the liver, and lifting up this organ, and general massage of the abdominal area. In addition active movement of the muscles of the abdomen and perineum should be made, as well as respiratory gymnastics. Bi-manual massage of the uterus and annexa is generally useless and even harmful. Direct manipulation of the uterus is alone permissible for the purposes of causing the organ to contract or restoring it to its normal position, unless the upper venous channels have already been well opened up by the procedures just described, and all acute local inflammation has disappeared. External massage and surgical treatment are not mutually exclusive, but complementary.

PRESSE MÉDICALE.
August 2, 1913.

Treatment of Hyposphyionic Conditions.—Alfred Martinet discusses the therapeutic management of cases in which hyposphyxia—diminished pulse pressure, with diminished arterial blood output and increased blood viscosity, resulting in venous stasis and circulatory sluggishness—is combined with hypoporia—glandular insufficiency, especially of the digestive and the internally secreting glands.—these two conditions so reacting upon each other as to form a vicious circle. The treatment should consist, first of all, in measures to activate and strengthen the circulatory function, viz., the administration of strychnine, stryoptine, epinephrin, and pituitary extract, singly, simultaneously, or alternately; progressive physical training, beginning with rubbing, massage, passive movements, active movements, and respiratory gymnastics, and ending with dumbbell and resisted exercises, walking on flat or inclined surfaces, etc.; and in addition, subcutaneous injections of oxygen, which stimulate the circulation, increase the amplitude of the respiratory movements, augment the hemoglobin percentage, and lower the viscosity of the blood.

At the same time, measures should be instituted to reestablish proper glandular activity. Half an hour before meals, the patient should take a half wine-glassful of lukewarm vichy water, followed in twenty minutes by a small amount of some bitter preparation. During meals, pepsin in an elixir, or in natural gastric juice, and after meals, extracts of the whole pancreas and duodenum should be taken. These digestive remedies should be given only a short time, lest the natural secretory reflexes become in part inhibited. Thyroid and ovarian extracts may be alternated with the epinephrin and pituitary extract, already referred to as cardiovascular remedies. With this treatment the author has had excellent results in cases of hyposphyxia occurring after infectious diseases, mania, neurasthenia, and in the pretuberculous. Improvement was also noted in congenital conditions accompanied by hyposphyxia.

Action of Diphtheria Antitoxine on the Diphtheria Bacillus.—P. J. Ménard asserts that the soluble toxine of Bacillus diphtheriae is not the sole cause of diphtheria manifestations, certain proteins and lipoids in the bacillus also being responsible. Experiments showed that diphtheria antitoxine, far from killing the bacillus itself, is a better culture medium for it than other media commonly used, the organism remaining alive for months in the serum, merely losing for a time its toxicity, its power of forming false membrane, and its staining affinities. Tests in vivo, viz., in guineapigs and rabbits, showed that the virulence of diphtheria bacilli was not diminished by its passage through animals that had received antitoxine, but in some cases it was increased. These findings illustrate the fact that, in spite of the marked antitoxic value of the specific serum, it does not prevent the germ from vegetating, whether virulent or not, for prolonged periods in the throats of persons to whom the serum has been administered. It is advisable, therefore, to practise local antiseptic in the throats of diphtheria patients, great care being taken, however, not to injure the mucous membrane.

BRITISH MEDICAL JOURNAL.
August 16, 1913.

Chemotherapy.—Paul Ehrlich here presents one of the clearest and most concise and understandable general summaries of the subject of chemotherapy yet published in English. The paper commends itself especially to the general practitioner, being free from the usual discursive and highly technical arguments. He cites a number of newer examples of the establishment of strains of
infecting parasites which have become "fast" or resistant to the chemotherapeutic agent aimed at their destruction. Such a drugfast strain is the result of a failure to sterilize the tissues of the host at a single, or with at most a few injections. This possibility, together with the difficulties encountered in man of giving a sufficient dose to bring about a complete sterilization without endangering the welfare of the patient, forms the basis for the use of combined chemotherapeutic measures. In this combined therapy use is made of the fact that most forms of infecting parasite have several receptors capable of uniting with different chemical molecules. These different molecules must have affinities for the parasitic receptors greater than their affinities for the tissues of the host. The different substances used as toxic agents, and to which the anchoring molecules are to be attached, are thus brought to act almost solely upon the offending organism. The combined actions in such cases may be simple summations of the several individual actions, or, more commonly, they are multiples of such actions. Thus, while the parasite is attacked in an intensive manner, the host is left unharmed, for, owing to the slight affinity existing between the several drugs used and the tissues of the host, their toxic actions are not multiplied, or even added, with respect to him. Salvarsan and neosalvarsan are defended, and the nerve lesions which are often seen after their use are once more attributed to the liberation of toxines through the destruction of foci of the spirochetes.

The Necessity for a More Thorough Control of the Milk Supply in Combating Surgical Tuberculosis in Childhood.—Harold J. Stiles and his assistants have studied sixty-seven consecutive bone and joint cases in children, finding the bovine bacillus in sixty-one per cent., human in thirty-four per cent., and both types in three cases. In those cases in which the human type of bacillus was found there was consumption in at least one member of the family in seventy-one per cent. of the instances. In all the children less than a year old the bovine bacillus was the one present, and each of these cases had been fed entirely on cow's milk. Seventy-two cases of tuberculosiis of the cervical glands were operated on, and in ninety per cent. the infecting agent was the bovine bacillus. In none of the sixty-five cases of bovine infection was there a history of pulmonary tuberculosis. In three cases of infection by the human type each had a family history of pulmonary tuberculosis. In fifty-one of the cases the first gland to be infected was found to be the tonsillar lymphatic one. A further interesting finding is, that of the tonsils removed from ninety consecutive children having no clinical evidence of tuberculosis, ten per cent. showed tuberculosis when inoculated into guinea-pigs. As a result of these observations, Stiles calls attention to the need for greater control of the milk supply.

LANCET.

August 16, 1913.

The Dosimetric Method of Administering Chloroform.—Dudley W. Buxton lays down eight principles as underlying this method. 1. Chloroform acts upon the human tissues directly in proportion to the strength of its vapor contained in air or other gaseous admixture, or if it is in solution, in direct proportion to the strength of its vapor as given off. 2. Its action is progressive in the sense that with a constant dilution administered over a long period the resulting narcosis continually deepens. 3. Although similar in kind, its action is different in degree on the different body tissues. 4. Chloroform ultimately acts as a protoplasmic poison, such action varying directly with the strength of the chloroform vapor which enters the organism. 5. There is no reason to believe that the action of the drug is capricious, but there is every evidence to show that it acts more vigorously on abnormal tissues. 6. There is a definite strength of vapor which in all cases will induce anaesthesia; this is two per cent., for man, when this is exceeded deeper narcosis results which interferes detrimentally with the functions necessary for life, for example, the circulation, respiration, or the metabolism. 7. Further, there is a definite proportional strength of vapor which will maintain anaesthesia, once it has been induced, without increasing the depth of the narcosis; this percentage varies inversely as the length of time during which the vapor has been inhaled. 8. Both the concentrations needed for the induction and for the maintenance of anaesthesia are at the maximum for the adult of normal physique, while for persons of impaired vitality and for children they are lower. This statement is more especially true of the concentrations needed to maintain anaesthesia after its induction. Buxton says that when the limit of two per cent.—the maximum for healthy adults—is exceeded the patient is always carried into the danger zone, this being associated with a dangerous fall in blood pressure and depression of the respiratory and cardiac centres. From wide experience, Buxton advocates the use of the Vernon-Harcourt regulator for the control of the percentage strength of the chloroform in clinical use. He combines oxygen with his chloroform administrations on the theory that its use serves to maintain the vitality of the tissues and lessens shock. He concludes by saying that he thinks that the dosimetric method is the only safe way of administering chloroform, and that by its use the dangers are abolished or rendered negligible.

BOSTON MEDICAL AND SURGICAL JOURNAL.

August 21, 1913.

Description of an Abdominal, Lumboiliosacral Support and Its Uses, Advantages, and Limitations.—H. W. Marshall describes the following apparatus for the support of the lower part of the spine and of the abdomen. It consists of two upright steel straps, each fitted to the contour of the lumboiliosacral region, one placed on either side of the spine, overlapping the ribs above and extending below to the lower limit of the sacroiliac articulations. Cross bars of steel, slightly bent to make room for the bony spinal processes, or riveted to the ends of the longitudinal ones, thus forming a single light rectangular steel splint. Metal buttons are riveted to each of the lower corners and upon each of the upright steels near the top, making four in all. The belt consists of three or four strips of webbing, which are fitted snugly while the patient is in a standing posture. It encircles the abdomen, extends approximately from the umbilicus to the symphysis.
in front, passes just above the trochanters of the femora to extend low enough in back to include the sacroiliac joints. Adjustable straps and buckles are stitched in rows to the belt near the midline in front, also in other rows near the midline in back, after a three or four inch strip has been cut from the latter locality dividing the belt in halves. Additional tightening, if the webbing stretches, is thus made possible. Flexible thin steels keep it from wrinkling, and eight buttonholes are made to fasten it to the steel splint. The belt is finished, except the buttonholes, while the steel parts are riveted together, without tempering. Then the belt is put on the patient, the steel splint bent so it will take the pull off the back from the abdomen. The buttonholes and buttons are located accurately, the steel parts are tempered and padded, and the two portions are buttoned together to complete the apparatus.

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.
August 22, 1913.

The Teaching of Therapeutics, by R. L. Wilbur.—See this Journal for July 5, p. 40.

Care of the Umbilical Stump, by F. L. Adair.—See this Journal for June 28, p. 1360.

Operative Treatment of Cancer of the Stomach, by W. J. Mayo.—See this Journal for June 28, p. 1360.

Experimental Transplantation of Intestine after Extensive Excision of the Sigmoid, by J. S. Hersley.—See this Journal for June 28, p. 1360.

What Can Be Done in Cancer with Röntgen Rays, by W. A. Pusey.—See this Journal for July 5, p. 50.

Precocious Menstruation, by F. P. Gengenbach.—See this Journal for July 5, p. 41.

The Future of the Medical Man.—J. G. Adami states that true knowledge consists, not in cognition, nor in the possession of a store of facts, but in the capacity to use them, and urges the importance of hospital internship in order that the student may learn the art, as distinguished from the science, of medicine. Speaking of medicine as a business, he says that it is certainly true that an increasing proportion of medical men is more concerned over the means of improving its balance in the bank than over the means of improving the health of its patients, and regards social success as more to be considered than professional capacity. Deploiring this tendency, he extols a high ideal of service in medical practice, believing that to-day and in the future, as even in the past, care must be, not for ourselves, but for our fellows. "If we desire not so much an upper seat in the synagogue, as a serene mind and self respect as the greatest of worldly possessions, let us not trouble ourselves about money making."

Röntgenotherapy in Measured Massive Doses.—S. Lange says that the problem for the röntgen therapist resolves itself into the fulfilling of three requirements. 1. Certain cells or tissues must be supplied with the kind of rays or quality of rays which they can absorb. 2. The rays supplied to these must not injure the surrounding overlying or underlying tissues. 3. The rays must be supplied in sufficient number or quantity to bring about the desired changes. It would seem that the ability to administer the massive dose is a sine qua non of successful röntgenotherapy. After the technic of measuring the dose in certain units has been mastered, the problem of how many units to give is still uncertain and to a large extent dependent upon individual judgment. In determining the amount required for the treatment of any condition it must be remembered that the biological or active dose is the physical (or crude) dose multiplied by the coefficient of susceptibility of the tissues under treatment. In applying these heavy doses we should not be unmindful of the possible dangers and possible late effects from the repetition of such doses; and it is apparent that a method like this must remain in the hands of those specially trained and skilled in röntgenology.

The Minimizing of Insanity.—M. L. Neff finds that the preventable cases of insanity contribute only a small part of the permanent institutional population. Hospitals for the insane are filled with the accumulating cases of dementia praecox, manic depressive insanities, and unclassified psychoses. The underlying somatic causes which produce mental symptoms in these groups we do not know, and it is idle to talk of prevention, in a strictly medical sense. From the advent of the psychopathic hospital we hope much, though we cannot ignore the possibility that its various other functions may overshadow its function as a hospital in which real therapeutic work shall take precedence of everything else. This concerns the problem of minimizing insanity quantitatively; and the author then considers it qualitatively, and asks, How far can the degree of insanity be minimized? How much of the mental deterioration to which we have become accustomed could have been prevented? In our hospitals for the insane that inhuman thing which is conned by the term "institutionalism" has brought about conditions, under which none of us could remain normal. The patient becomes a sort of human palimpsest, and only the mental archaeologist could say how much of that which can be deciphered is of the original writing. There are four main reactions to prolonged enmity—reactions not an essential part of the insanity, but such as would occur with ourselves if similarly placed: namely, apathy, violence, untidiness, and the elaboration of delusions, fears, and obsessions. The great majority of patients who have not been kept busy and contented will fall into one of these four classes; and the problem, then, is to find normal stimuli, incentives, rewards, and human reactions for the patients. Only by treating the insane just as we ourselves would like to be treated will practical and effective ways of helping them be found. The "normal areas" of the patient's mental life are the ones on which to base his treatment, rather than the abnormal ones. Since we cannot avail ourselves of the major stimuli of life, we must utilize to the fullest extent the minor ones. All forms of self expression should be developed in an institution, employing the play motive as largely as possible. The activities furnished for patients should be as normal as possible in every way, including carefully...
The Inheritance of Epilepsy.—D’Orsay Hecht, in summarizing the facts which seem to him worthy of emphasis in a discussion of this subject, says he would urge the following points: 1. Human society must concern itself more and more with the qualities in man which are physical and vital, as opposed to those which are mental and moral. 2. In heredity we find the most potent factor in the evolutionary process of man. 3. Environmental influences may modify, but do not increase, our original endowment. 4. The essential thing in the preservation of the race is physical fitness, and inheritance, in its turn, is the essential and most to be desired thing in the development of such fitness. 5. The methods by which we are to-day better able to explain the qualities and attributes inherited by man are perhaps those referred to as Mendelian and biometric. It should, however, be thoroughly understood that no biological phenomena, either in full or even in large part, meet the theoretical expectations of either method. 6. Still, the inheritance of epilepsy is very worthy of being subjected to an analysis, Mendelian or biometric, in the hope that valuable data may be secured, and in the end enable us to invoke the proper measures against the spread of the disease. 7. The studies already made are highly instructive and suggestive, although there are many sources of error which appear to be almost impossible to overcome. 8. Society has the moral right to interfere with the continuance of any human stock definitely known to be unalterably unsound and, on the assumption that an overwhelming proportion of epileptics are of this type, the plan of segregation, efficiently and scientifically carried out, is a just one. 9. The act of sterilization, in the light of our present knowledge, is still open to criticism and objection, and may, therefore, be considered premature and, as a measure of legislative interference, should not be endorsed. 10. The mildly inferior epileptic constitutes a very great menace, and one concerning which scientists are not prepared to make recommendation. 11. There is greater need to point out the difficulties and discrepancies encountered in eugenic research than to proclaim its triumphs; it is vastly more in need of students who will investigate and diagnosticate the agencies contributing to the illnesses of the race, than of amateurs who announce the remedies and shout the cures.

Feeblemindedness and School Children.—E. B. McCready believes that the question of the responsibility of the public school to the feebleminded child should be considered in relation, 1, to the child himself; 2, to his fellow pupils; 3, to society in general. Neither restriction of marriage nor sterilization presents any real promise of assistance in the solution of the problem of adequate care and prevention of feeblemindedness, and the only means by which the desired end can be accom-plished is by segregation in institutions of all feebleminded persons, with the possible exception of those who can be properly cared for at home under the supervision of the proper authorities. In the United States which are now a part of the school system in nearly all our large cities, the feebleminded child may, and usually does, progress up to a certain point; but the author is convinced that he should be allowed to remain in the special class only a sufficient length of time for his condition to be accurately diagnosticated, or until a place can be found for him in a suitable institution.

The Uterine Syndrome.—This, G. K. Dickenson says, is a statement of the basic symptoms of the functional disturbances of the uterus. As there are three channels by which the economy is made cognizant of local conditions, so there are three classes of syndromes: Symptoms expressed through the branches of the spinal nerves, disturbances brought about by irradiation of the sympathetic proper, and either loss or imbalance of the internal secretions of the ovary. Through the pubic and sacral nerves passing to the sympathetic we have an appreciation of pain, the reflex phenomena induced being referred peripherally through either branch of these nerves. Through the sympathetic we have another type of syndrome, the visceral. Steady inhibition through this symptom leads to intestinal stasis, and this symptom is further aggravated by the pain often felt in defecation; which leads to a postponement of the evacuation act, vesical tenesmus, and dysuria. The third syndrome, due to loss of ovarian tissue or its gradual absorption (popularly known as “change of life”), is brought about by an incomplete balance of the internal secretions. The practitioner should be able to balance up the many symptoms and signs coexisting, weigh out their importance, and rationally deduce a helping therapy; remembering that tension is generally the original causative factor in the various lesions inducing these syndromes.

Prolonged Precipitate Parturition Due to Disengagement of the Disproportionate Head, by A. E. Gallant.—See this JOURNAL for August 16, p. 350.

A Sphygmomanometer of New Principle.—In the course of blood pressure research at the Harvard Summer School G. Van N. Dearborn has been again impressed with the needless clumsiness and general indeterminateness of the cuff sphygmomanometers in general use, and states that the simple and inexpensive instrument which he presents is the more or less tentative result of the obvious need for a more physiological form. This consists merely of a properly adapted endpiece of an ordinary stethoscope firmly attached by a screw thread to a spring dynamometer with a transparent handle (having at the bottom a flat vulcanite ring, one centimetre thick), by which it may be readily grasped and pressed against the artery. The dynamometer has two scales, one giving the reading of the brachial blood pressure in the conventional millimetres of mercury, and the other in absolute grammes. If found to be desirable, the long cylindrical spring may be replaced with one of spiral form, thus greatly shortening the instrument.

2. Prostatectomy

is the best treatment for enlarged prostate.

It would appear, from his investigations, that prostatectomy in the aged is nearly as safe as in younger men, and is good surgical practice wherever indicated, and whenever the physical condition of the man will warrant it. The consensus among a number of genitourinary surgeons in this country as well as abroad, consulted by the author by letter, was that age is no bar to prostatectomy, and that this should be performed whenever practicable. He states that he was stimulated to make the study by a personal experience in two successful cases of prostatectomy by the perineal route in men ninety years of age. Reports are given of two cases in patients of this age, one of which was operated upon in 1909, and one early in the present year.

FATAL CASE OF OIL OF CEDAR POISONING.—R. L. Thompson and J. S. Archibald report this case. The patient was a married woman of twenty-two, previously healthy, who was found dead in bed. On the floor was a small amount of vomitus, tinged with blood. There was a history of one month's suppression of the menses, and at the inquest the fact was brought out that she had at previous times made use of cedar oil, but with no ill effects. The authors give the post mortem findings and the results of the microscopical examination, and among their conclusions are the following: In certain localities oil of cedar has been quite generally used as an abortifacient. In most instances the drug seems to be harmless, both to the individual and to the fetus. Occasionally, however, as in this case, a small dose acts as a fatal poison; and, strangely enough, as also in this case, a person who has been a more or less habitual user of it at monthly periods, without ill effect, may succumb to a small dose. A few experiments made on dogs served only to bear out the severe action, or the complete lack of action, of oil of cedar. In the animals employed they were unable to kill with the first use. In several instances rather large doses were given: but the same animal was killed by a smaller dose from one to three days later. The autopsy findings corresponded very closely to those in the human. Since attention has been called to drug supersensitivity, there are increasing numbers of cases of poisoning which have to be considered as anaphylactic phenomena. Among these drugs are iodoform, iodides, antipyrine, and arsenic (salvarsan and neo-arsenical). It seems, from the case now reported, that oil of cedar may be included in the list.
Proceedings of Societies.

MEETING OF THE INTERNATIONAL CONGRESS OF MEDICINE

 Held at London, England, August 6 to 13, 1913.

This Congress was the most remarkable Congress of Medicine which has ever taken place. It was remarkable in the number of those attending, nearly 8,000 medical men from all parts of the world having put in an appearance; in range of subjects which treated of everything connected directly or indirectly with medical science, and perhaps above all in the harmony and good feeling which characterized the proceedings from beginning to end of the meeting. There was a marked go and vivacity throughout, but at the same time a spirit of tolerance prevailed. Racial and international animosities were distinguished by their absence, a fair recognition of the claims of others was displayed on all hands, and the conference passed without any jarring notes whatever.

Of course, it is impossible not to compare the meeting just over with that other International Congress of Medicine held in London so far back as 1881. With regard to the outstanding figures present at each, the conference of 1881 was preeminent—Koch, Lister, Pasteur, Huxley, Virchow, Paget, Hughlings Jackson, Volkman, Charcot, Verneuil, Austin, Flint, Billings, Baccelli were all there. At the conference of 1913 there were indeed some very eminent men but no such giants of science, of medical science, and chemistry, with the exception of Dr. Paul Ehrlich as the most renowned of those who took part in the proceedings of thirty-two years ago. In all other particulars the 1913 meeting was incomparable. In 1881 there were fifteen sections, while in 1913 there were twenty-three sections and three subsections and the demonstrations of the wonderful increase of medical knowledge which were therein given were almost staggering. At least, one pronouncement of great importance was made and those general addresses which were delivered were of high scientific and literary value. Dr. Harvey Cushing's address was of exceptional merit, but the general addresses will be referred to in more detail, later on. From a social aspect, the meeting was a triumph, receptions, garden parties, dinners and so on were numerous, and the medical men of London left no stone unturned to render the visit of their American and foreign confères one to be remembered, and meted out hospitality with unstinting hand. The headquarters of the conference was that tremendous building situated in Kensington, raised to the memory of the late Prince Consort, and the sectional meetings were held in rooms in the University of London, the Imperial College, the Royal School of Science, the School of Art and the Central Technical College. All these buildings are within easy reach of the Albert Hall. Sectional meetings also took place in the buildings of the Royal College of Physicians, the Royal Society of Medicine, St. Thomas's Hospital, the Royal Army Medical College at Millbank and the Royal Dental Hospital. The morning sessions were given over to discussions on stated subjects, which were introduced by well known authorities.

The organization of the meeting was excellent, without which no meeting can be a success and, when the immense unwieldy size of the gathering is taken into consideration, the task set the secretary general and his coadjuvants may be better imagined than described. Dr. W. P. Herringham, the secretary general, and his aides performed their duties in so able and efficient a manner that the machinery worked smoothly and but few of its parts got out of order.

Before, however, reviewing the happenings of the congress in a necessarily somewhat brief manner, it will not be out of place to describe a meeting which took place the day before the formal meeting. This was the Fourth International Congress of the Medical Press in the Jehangir Hall of the Imperial Institute. Fifty or so representatives of the foreign and British medical press were present and Dr. Squire Spriggs, editor of the Lancet and president of the British section of the International Press, was in the chair.

Dr. Lucas Championnière, president of the association, opened the proceedings with a short speech, after which Dr. Squire Spriggs on behalf of the British branch replied. Dr. Spriggs, who spoke partly in French and partly in English, referred to the work done by the British medical press and especially by the independent organs in influencing the government to modify the Insurance Act in its original form to the great benefit of the medical profession in Great Britain. He pointed out that medicine had thus become a real force in the politics of that country, while at the same time the ordinary scientific work of medical journalism had not been neglected. Dr. Raoul Blondel, general secretary of the association, then read his report followed by a report on medical terminology.

On the conclusion of Dr. Blondel's paper, the congress adjourned for luncheon, given by the editor of the Lancet to the members of the congress, at the Hyde Park Hotel.

The afternoon session of the congress was taken up with a discussion of Dr. Blondel's paper on medical terminology and the presentation of a report by Dr. C. Posner, editor of the Berliner Klinische Wochenschrift, on the Responsibility of Medical Journals with Respect to Advertisements. Dr. C. Dejace (Belgium) was elected president of the association and R. Blondel and Dawson Williams were reelected general secretary and treasurer respectively. The congress will meet again at the next International Congress of Medicine.

The inaugural ceremony connected with the opening of the congress proper took place in the Albert Hall on the morning of August 6. It was an impressive scene, and the word impressive describes it better than any other. The gathering was essentially that of learned men and a person of little discernment could see at a glance that it was one out of the common. Although the majority of the audience were attired in dark clothes, the mise en scène was not gloomy. Many ladies were present in costumes of bright hue, and these together with the uniforms of naval and military medical officers of the various nationalities and the gowns and hoods.
of academic bodies relieved all appearance of sombreness and gave an air of brightness to the vast assemblage. Whatever, too, may be faults of the Albert Hall from an acoustic standpoint, at least in one respect it demonstrated its merits as a meeting place. It is well ventilated and airy, a quality in happy contraddistinction to some of the halls in which previous meetings of a like nature have been held. Prince Arthur of Connaught, who had been deputed by the King to perform the inaugural ceremony, at eleven o'clock sharp appeared on the platform and without delay, in a clear voice, gave the opening address. Then Sir Edward Grey, the British Minister for Foreign Affairs, welcomed the congress on behalf of the government in an apt and commendably brief speech, after which the president, Sir Thomas Barlow, delivered the Presidential Address. The address was full of good things and well expressed, but space will permit of no more than a few short comments. He emphasized the progress of bacteriology, and paid high tribute to the splendid hygiene work done by American medical men and sanitarians in Cuba, in Panama, in the Philippines, and in Costa Rica. He referred to the magnificent triumphs of surgery and said that the supreme gain after all is that many more useful lives are saved than in the last generation, that the realm of grave and hitherto incurable disease is invaded on every side, and that the danger of operation is retreating to a vanishing point.

Speeches were afterward made in a variety of tongues by the chief representative delegates from other lands, each of whom was presented by Dr. W. P. Herrinking, the secretary general, and the inaugural ceremonies were over.

In the afternoon of the same day the address in medicine was given by Doctor Chauffard, professor of clinical medicine in the University of Paris. A feature of the meeting and one that forcibly struck a person unaccustomed to hearing speeches in a foreign language was the eloquence, facility of expression, and clear enunciation of the French speakers.

Dr. Chauffard said in part, that prognosis was a matter that had confronted the profession daily since the origin of medicine. Diagnosis and prognosis were inseparable. Their progress had been interdependent. The methods of prognosis, however, were being modified, its limitations were being carried forward every day; it was in a state of perpetual transformation. He therefore thought it was a favorable moment to consider the stage it had reached, and for an appraisement of our acquisitons and desiderata. In the Hippocratic period the value of prognosis was placed in the front rank, and the general conditions and objective signs were studied in the most minute way, the only means indeed available for discovering data from which to form judgments. The principle laid down was that “the body should always be considered as a whole” and “all things should be judged by the study of signs and the estimation of their relative value.” Plato upholds the same idea in his “Charmides” when he says; “It is impossible to cure a part without the whole.”

It was not until modern times that Augenbrugger and Corvisart by the introduction of percussion, Laennec by the invention of auscultation and Richard Bright by the creation of renal pathology pointed the way to the transformation of medicine. Direct exploration became possible and efforts were made in Laennec’s own words “to place in regard to diagnosis internal organic lesions on the same lines with surgical diseases.” To detect the lesion in the living subject, to identify it in the cadaver, and to deduce therefrom diagnosis and prognosis, such became the system of what was to be for more than half a century, Organism, a noble system which contained a large share of truth, but a narrow doctrine which tended to confuse the lesion with the disease which caused it.

Claude Bernard advanced diagnosis and prognosis by seeking novel cases in the study of functional disorders, and we were still journeying in the same direction.

Our modern methods attempted to make diagnosis, as precisely as possible, a representation of the pathological condition of the system as regards its genesis, its present equilibrium, and its future evolution, and a diagnosis thus established amounted almost to a scientific prognosis. In any event, the two were very proximate modes of considering the same facts. Nevertheless, immediate prognosis should be completed by research of remote prognosis, an all important idea introduced into science by Borrilland’s discovery of rheumatic endocarditis.

Chronic infections, syphilis and tuberculosis afforded striking evidence of the importance of the remote consequences of disease. It might almost be said that nothing was forgotten in the system. The most conclusive proof of this was provided by Charles Richet’s discovery of anaphylaxis. The individual prognosis, present or future, was completed by notions concerning the family, the collective prognosis, the social prognosis.

It was the latter that justified our law enforced measures of prophylaxis and preventive vaccination; it was from it that Sir Francis Galton’s labors evolved the new science of eugenics. In conclusion, Professor Chauffard said: “Medical prognosis is, as it were, the corollary and the practical application of diagnosis; it borrows its methods, it follows its progress. In the course of its modern evolution it has taken its share of all the advances of scientific medicine; it has not ceased to walk in the paths of clinical analysis and of experimental pathogenesis; its aim has been raised, its scope extended. It appears as the synthesis of medical criteria; it precedes, checks and justifies treatment and prophylaxis. If we consider the constant advances of medical prognosis and the many opportunities it affords us for ascertaining the lessened gravity of disease, we can better appreciate the progress already achieved and our efforts will thus meet with their greatest rewards and incentive.”

The address in surgery was given in the Albert Hall in the afternoon of August 7. Dr. Harvey Cushing’s address was acknowledged by all who heard it, or read it, to have been a magnificent contribution to medical literature, and a really great defense of pathological and physiological experiment. In eloquent language he reviewed the progress of surgery during the past thirty years and
showed unmistakably how greatly human suffering had been relieved through the results of the investigations of physiologists and surgeons. He likewise laid stress upon the changed conditions under which it is now imperative to pursue medical education consequent upon the rapid advances made in the knowledge of disease.

The title of Doctor Cushing's address was "The Realignments in Greater Medicine, Their Effect upon Surgery." Doctor Cushing said in part that the weakest point in the opposition to experimentation on the score of cruelty is that the animals whose preservation is desirable benefit as greatly as man. A sentiment has arisen which would exempt the canine species from experimentation. But had such a law been put on the statutes Cohenman's discovery of the bacterial cause of distemper and of a successful method of inoculation against this most fatal and distressing canine disease would have been impossible and the same is true of the fatal malignant jaundice, a parasitic disease conveyed by the bite of a dog tick, which is so prevalent in some parts of the world as to make the rearing of dogs impossible, and for which Nuttall has found an effective remedy and means of prevention. What a credit to the societies for animal welfare could such discoveries have come through their own efforts rather than through the efforts of those whose methods of research they are prone to question.

As a therapeutic measure human vivisection, to use this cruel word in a sacred sense, has almost wholly lost its terrors. The triumphs of surgery stand beside those of hygiene and preventive medicine as the notable medical achievements of these thirty years. Surgery has been one of the great factors in the present realignments of medicine, from Lister and Pasteur as their fountain head the great streams of progress have flowed, in the case of the individual into the art of surgery, and in the case of the community into prophylactic medicine. Even the physician who has so long held himself aloof from anything savoring of handicraft, returns to it with that useful instrument, the hollow needle; and paracentesis, lumbar puncture, and the extraction of blood for diagnostic, or the administration of drugs and sera for therapeutic purposes, by a minor surgical act, are all acknowledged as part of his therapeutic resources. By a strange transformation, too, he has become the phlebotomist, and the venesections and cuppings, formerly the overworked province of the barber surgeon, are largely practised by him to-day. Billroth said some thirty years ago: "Die innere Medicin müsse mehr chirurgisch werden," and this seems to be what is taking place.

The application of surgical principles, whether in laboratory or clinic, is constantly becoming more general. The slipper of surgery has been found to fit the Cinderella of medicine, experimental pathology, whose coach now has devoted outriders representing all departments. Observations which even in the hands of a Bernard or a Colonheim were impossible before the era of reactionless wound healing now become possible; not only may the counterfeit of conditions of disease be produced and studied without the complicating element of sepsis, but with surgical methods the Pawlows and Carrels of the laboratory bring about altered con-
therapeutic agencies which contained such powerfully acting radicals as arsenic and mercury.

The practical results of Doctor Ehrlich's system of treatment had been best shown in the group of diseases caused by spirilla. Thus a tropical scourge known as yaws had been so greatly overcome in Surinam that a hospital which contained formerly an average of three hundred patients was closed altogether after the introduction of the salvarsan treatment, as a single injection sufficed to cure all the patients but two. In the case of Vincent's angina the local application of salvarsan to the inflamed parts was sufficient; and there were a number of other diseases, both in man and in animals, for which the treatment was valuable.

Doctor Ehrlich professed himself an optimist as regards the outcome of the fight against disease and pointed out that discoveries with respect to the modes of spreading disease had been made good use of in the fight against epidemics and for propylactic measures and had brought about improvements beyond all expectations. In addition, in the battle with diseases which had already broken out, advantage had been derived from such discoveries, the most remarkable example of this being diphtheria antitoxine. Now that the liability to, and danger from, the disease were greatly circumscribed, so far as epidemics and the spread of many other maladies were concerned, the efforts of chemotherapeutics were directed, to as great an extent as possible, to fill up the gaps left in this circle and more especially to bring healing to diseases in which the natural powers of the organism were insufficient. Further, it was his belief that now, when definite and sure foundations had been laid for the scientific principles and method of chemotherapeutics, that the way was in sight, not always easy, but yet practicable. There were many valuable indications that in a series of diseases, smallpox, scarletina, typhus, exanthemata, and, above all, infectious diseases caused by invisible germs, the prospects of success were brightening. In contradistinction, however, to these superparasites the ordinary or common bacterial diseases, diseases due to the streptococcus and the staphylococcus, coli, typhoid, and dysentery, but, above all, tuberculosis, would still require a hard struggle. Nevertheless, he looked forward with full confidence to this development also, and might, without being set down as an optimist, put forward the view that in the next five years we should have advances of the highest importance to record in this field of research.

A very valuable general address was given by Doctor Bateson, of Cambridge University, on Heredity. Probably Doctor Bateson is the greatest authority in the world on genetics and his review of the present position of this science was intensely interesting. The address was not given in the Albert Hall, but in the Jehangir Hall of the University of London, in order that he might illustrate his text by slides showing in diagrammatic form the history of certain abnormalities persisting from generation to generation. In his introductory remarks Doctor Bateson pointed out that to the penetrative foresight of Francis Galton it was evident long ago that the aspects of physiology connected with family history must one day become a chief preoccupation of reflecting minds. But no one before the rediscovery of Mendel's work had ventured to imagine that the confusion, the paradoxes, the capricious disorder of the phenomena of descent were, in a very great measure, capable of a simple and ready analysis. It is this knowledge which has given to genetic science a position paramount among the branches of physiology, showing that in accurate genetic analysis a means is given not merely of elucidating the interrelations of parent and offspring, but of contributing also to a right interpretation of various special problems of pathology and anthropology, perhaps, also to a true understanding of the course of human history. It would be impossible in the space at disposal to intelligently discuss the various problems of genetics so ably dealt with by Doctor Bateson; suffice it to say that the address was a clear and comprehensive review of the whole question. There was, however, one portion of his address to which reference should be made, inasmuch as it refers directly to certain action and contemplated action in the United States with regard to the regulation of marriage. On this point Doctor Bateson expressed himself as follows: "It is one thing to check reproduction of hopeless defectives, but another to organize a wholesale tampering with the structure of the population such as will follow if any marriage not regarded by officials as eugenic is liable to prohibition. This measure we are told is actually proposed in certain of the United States. Nothing yet ascertained by genetic science justifies such a course, and we may well wonder how genius and arts will fare in a community constructed by legislators in this way."

The last general address was delivered by the Right Honorable John Burns, president of the Local Government Board, and dealt with the economic view of health. It was eminently instructive and teemed with statistics, but there was nothing original or even novel in it. The address was interrupted frequently by militant suffragettes of the male and female sex who were promptly ejected as soon as their voices were heard and their situation located.

After the conclusion of Mr. Burns's address the formalities of closing the Congress were proceeded with. The invitation of the Bavarian Government and of the city and University of Munich to hold the next International Congress of Medicine there, in 1918, was accepted. The following award of Congress prizes was announced: The Moscow Prize to Dr. Charles Rielert, of Paris, for his work on anaphylaxis. The Paris Prize, to Dr. A. von Wassermann, of Berlin, for his work on experimental therapy and immunity. The Hungarian Prize to Dr. A. E. Wright, of London, for his work on anaphylaxis. The report of the Permanent Committee, which was adopted, contained a number of resolutions, sent up by the sections, among them being the following: That sensible of the ravages wrought by syphilis on the health of the community, and deploring the inadequacy of existing facilities for checking its dissemination, the International Medical Congress calls upon the Governments of all countries here represented: 1. To institute a system of confidential notification of the disease to a sanitary authority, wherever such notification does
not obtain. 2. To make systematic provision for the
diagnosis and treatment of all cases of syphilis
not otherwise provided for. With regard to vivi-
section the following resolution was sent up: That
this Congress records its conviction that experi-
ments on living animals have proved of the utmost
service to medicine in the past, and are indispensa-
table to its future progress. That, accordingly while
strongly deprecating the infliction of unnecessary
pain, it is of the opinion alike in the interests of
man and animals, that it is not desirable to restrict
competent persons in the performance of such ex-
periments.

The President, Sir Thomas Barlow, made a
farewell speech and the congress of 1913 was over.
Before concluding this brief, and in consequence
inadequate, account of the congress which has just
gone into the great past, it will be as well to com-
ten on two occurrences. One was the discussion
on salvarsan by the joint sections of Naval and
Military Medicine with that of Dermatology and
Syphiliography, and the other the discussion on
venereal diseases from the social standpoint by the
combined sections in Dermatology and Forensic
Medicine.

The discussion on salvarsan was opened by Dr.
Paul Ehrlich himself, who considered the bio-
chemical action on the spirochetae which caused the
disease. He believed that the action of the drug
was direct and required a third factor for its comple-
tion. This factor must be sought for in the tissue
fluids of the body. Salvarsan had no poisonous effect on the central nervous system, a fact which
had been proved by Ullmann of Vienna. Referring
to the causes of the commonly observed febrile re-
actions in its therapeutic use, he said that some of
these were due to technical errors of administra-
tion; in a second, large class they were due to the
drug being administered in the roseolar stage of the
disease, in which the whole body is saturated with
the spirochetae. The febrile reactions in such cases
were due to destruction of the spirochetes, and
the setting free of their toxine. It could be prevented by previous preliminary treatment with mercury, and it did not occur with subsequent
doses of salvarsan. It must be remembered that
salvarsan destroys all sorts of other organisms that
may be present, and the death of these may also
be productive of febrile reactions. As to recurrences,
about which so much has been heard, Doctor Ehr-
litch gave it as his opinion that they were due to an
insufficient treatment with salvarsan, and he thought
a good many deaths must be ascribed to the same
cause. Taking the chancre and general paralysis as the beginning of the end, respectively, of all mani-
festations of syphilis, he was of opinion that salvar-
san would effect sterilization in the first instance and
considerable alleviation in the second.

Lieutenant Colonel Gibbard, R. A. M. C., gave
evidence as to the remarkably beneficial effects of the
use of salvarsan in the British army, and de-
clared that it had revolutionized the treatment of
syphilis therein.

Dr. A. von Wassermann, Sir Malcolm Morris, Dr.
McCormack, Dr. McDonagh, Dr. Saalfield, Berlin;
Dr. Fordyce, New York; Dr. Schreiber, Magde-
burg; Dr. Ullmann, Vienna, all gave confirmatory
evidence, the last declaring that there was now no antisyphilis party. Some of the French medical
men, however, did not appear to be in favor of sal-
varsan, Dr. Levy-Bing, Paris, stating that his re-
results in the treatment of early cases of syphilis by
salvarsan had been unfavorable. On the whole, the
conclusions were decidedly favorable. Doctor Hata, whose name will be always associated with
that of the discoverer of salvarsan, related his ex-
perience of the value of salvarsan in the treatment of
syphilis and of a disease known as rabbit fever.

As for venereal diseases, the social evil, all who
joined in the discussion on this most important ques-
tion were agreed that steps should be taken to
prevent and control such diseases, of course, syphilis
especially.

Various measures with this end in view were sug-
gested, and, as mentioned before, a resolution was
passed and sent up to the permanent committee.
Among those who took part in this discussion were
Dr. A. Blaschino, Berlin; Dr. Ernest Finger, Vienna;
Major H. C. French, R. A. M. C.; Dr. Gaucher and Dr. Gougeret, Paris; Dr. Erik Pontoppidan, Copenhagen; Dr. Douglas White, Lon-
don; Mr. Ernest Lane, London, and Dr. Woods
Hutchinson, New York.

In the Section in Medicine, Sir William Osler, presi-
dent of the section, in the chair, a meeting was
held to discuss the cause and treatment of diabetes.
Doctor Dock, St. Louis, opened the discussion and
was followed by Doctor von Noorden. One
point in Dr. von Noorden's speech was traversed by
Dr. Saunders, Birmingham. The German author-
ity advocated whiskey to the extent of two or three
ounces a day in the treatment of severe cases of the
disease, advice which Doctor Saunders deprecated.

The functions of the ductless glands were dealt
with in the medical section in conjunction with the
Section in Physiology, the subject chosen for discus-
sion being "The Correlation of the Organs with
Internal Secretions and Their Disorders." Sir Ed-
ward Schäfer, of the Edinburgh University, was in
the chair. Among those who joined in the dis-
cussion were Sir William Osler, Oxford; Dr.
M. E. Gley, Paris; Dr. C. A. Ewald, Berlin; Dr. A.
von Korányi, Budapest; Dr. A. Biedl, Vienna; Dr.
William S. Thayer, Baltimore; Doctor Cushing,
Harvard University. The discussion was opened by
Doctor Gley.

Dr. Harvey Cushing gave an admirable account of
some of the researches and observations on affec-
tions of the hypophysis cerebri, or pituitary body.

In the Section in Surgery, Dr. Walter F. Bur-
rows, New York, read a paper on postoperative in-
testinal stasis and the intraabdominal use of oil.
Dr. F. H. Albee, New York, on bone transplanta-
tion, Dr. John B. Murphy, Chicago, on the clinical
results of arthroplasty and osteoplasty, Dr. A. L.
Soresi, New York, on the value of direct trans-
fusion of blood, its indications and technic, with
reports of over 600 cases. Dr. Ernest Laplace,
Philadelphia, on arteriothrombosis and thrombo-
ephelitis of the mesentery, and Dr. Charles Good-
man, New York, on arteriovenous anastomosis for
impending gangrene; a report of fifteen con-
secutive cases with arteriovenous anastomosis of
the femoral vessels. Before concluding it should be
mentioned that at the instance of the Section in Physiology, a resolution was passed upholding the value and importance of the experimental method of research. It goes without saying that the hospitals were thrown open to members of the congress and in many of them clinical demonstrations were given.

The entertaining was on a magnificent and profuse scale. A banquet was given by the Government at the Hotel Cecil on the evening before the congress opened, and after that the diversions of all kinds, public and private, provided were so numerous as to be almost confusing. Sir Thomas Barlow, the president, gave a soirée in the Natural History Museum, Kensington, on the evening of August 6th. Garden parties at Bethlem and at Regent's Park College; reception at King's College; dinner given by the Apothecaries' Society, and soirees at Grocers' Hall, Royal College of Surgeons, Royal Society of Medicine, and by the Royal Army Medical College was the special programme for August 7th.

On August 8th, there was a reception at Lambeth Palace and at St. Bartholomew's and St. Thomas's Hospitals, and a soirée at the Guildhall. On August 9th, an excursion to Brighton and a Royal Garden party at Windsor. On Sunday, August 10th, There were special services at St. Paul's Cathedral, Westminster Abbey, and Westminster Cathedral. The Zoological Gardens were open to members of the Congress. A garden party was given by Mr. W. Astor at Cliveden, and there was an excursion to Harrogate.

On August 11th: Excursion to Stratford-on-Avon; Masonic meeting; garden parties at Guy's and University College Hospitals; garden party given by Sir W. Lever; soirée given by Lord Strathcona. On August 12: Excursions to Oxford, Cambridge and Canterbury; and on August 13th: Excursion to Bath.

It would require almost unlimited space to describe the congress and its proceedings and entertainments in detail, but possibly enough has been said to convey to the readers of the New York Medical Journal a fairly clear impression of in many respects the most notable gathering of medical and scientific men ever collected in one place. There was a very large number of American representatives of medical science in all its branches present, more in fact came from the other side of the Atlantic than from any one country. It may also be said that they well upheld the ever rising reputation of American methods of medicine, surgery, and research.

Letters to the Editor.

A FURTHER COMMUNICATION ON OXIDATION IN CANCER

951 St. Mark's Avenue / BROOKLYN, N. Y., August 22, 1913.

To the Editor:

Since the publication of my letter on "Oxidation in Cancer" in the Medical Record, January 18, 1913, reports have come in. A physician in Marion, Ohio, reports a case of cancer of the mouth involving the morsset from the tumor of the jaw to the angle of mouth gradually improving, constitutionally as well as locally. His letter was received in April; he has not communicated with me since. Another case reported by a Chicago physician (last April) who states that the tumor scabs over; he does not state, but I think he means a broken down inoperable carcinoma, though he mentions a very advanced case. Another case, formula given by a physician of Syracuse, N. Y., but patient is in communication with me; in two to three months the tumor has become softer and smaller, and the general health fine. This is a case of inoperable sarcoma of the right breast. I have since added nuclein to my treatments, as leukosynthesis is produced by the saline portion of my formula. Metchnikoff states a trypsinlike ferment is found in leucocytes. Now, trypsin dissolves cancer cells. Nuclein produces xanthin bodies or purin bases; these bodies when combined with glucose render the acidity of the epithelium; as for instance kreatin and globin. According to Ross, nuclein overcomes the excessive alkalinity of the organism which is found in cancer. The hemoglobin formula together with its other activities does the same, for wherever there is an excessive alkalinity, the epithelium and cells are increased in movement.

The method of using formula and nuclein:

R. Sodii chloridi: 2.00 grammes; Potassii sulphatis: 0.070 grammes; Sodi sulphatis: 0.015 grammes; Calcii sulphatis: 0.09 grammes; Magnesii sulphatis: 0.025 grammes; Hemoglobin: 3.25 grammes; Aceta bullentis: 250 e. c. Dissolve the sodium chloride in the boiling water and filter, then add rest of the salts; when about to use add the hemoglobin. If hemoglobin is kept in this mixture for any length of time it is likely to decompose. This dose is taken by mouth, an hour or half an hour before breakfast, a half hour after breakfast (or half on an empty stomach).

R. Nucleini: 0.3 to 1.00 gramme. Sig: To be taken half an hour before the hemoglobin mixture. These formulas can be given intravenously, once a day, instead of by the mouth.

I wish to thank Dr. R. of Marion, Ohio; Dr. W. Lammond, of Chicago, Ill, and Dr. Price of Syracuse, N. Y., the gentlemen who have given the treatment a practical application.

Chas. F. d’Artois-Francis, M. D.

Book Reviews.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

This book is based upon a smaller one issued by Professor Schäfer in 1901, and contains descriptions of methods used in the classes of practical physiology in the University of Edinburgh. Electrical apparatus and methods in general are first considered, next their application in the study of muscle and nerve physiology, and finally, brief outlines are devoted to the physiology of the heart and vessels, secretion in general, respiration, reflex action, and the special sense organs. The illustrations are numerous and good, and the text well adapted for students. The book seems incomplete, however, in that no laboratory work on the blood, such as is generally required in American medical schools, is provided for. The section on the eye, likewise, appears inadequate in that no mention is made of the "artificial eye," which affords so promising a groundwork for future studies in retraction. Ferment action and the effects of various inorganic ions are other
subjects which, in view of their practical significance, one might now expect to find included in the student's "experimental physiology."

This is a work written expressly for students of medicine and cognate branches, and differs from Remsen's well known little book, which it greatly resembles in its mechanical features—in containing in particular the chemistry of the organic compounds which enter into the study of physiology, biochemistry, and pharmacology. After preliminary sections on the purification of substances and elementary analysis, consideration is given to such subjects of biological importance as the nature of solutions, osmotic pressure, ionization, colloids, surface tension, viscosity, etc. The customary description of the more commonly encountered organic compounds, with their mode of preparation and chemical relationships, is then begun, and occupies the remainder of the book. The author has striven to increase the value of the book as a work of reference and render it more complete from the standpoint of the student of medical sciences. On the whole, the book is very well the purpose for which intended. Mechanically, occasional deficiencies in punctuation are noticeable.

Cardiovascular Diseases. Recent Advances in Their Anatomy, Physiology, Pathology, Diagnosis, and Treatment. By Thomas E. Satterthwaite, A. B., M. D., L. D. D., Sc. D., Consulting Physician Post-Graduate, Manhattan State, Orthopedic, Babies', Champlain Valley Hospitals and North Eastern Dispensary; Member American Therapeutic, State, and County Medical Societies, American Medical and Greater New York Medical Associations, New York Academy of Medicine; Harvey Society; Life Member New York Pathological Society; Honorary Member Washington (D. C.) Medical and Surgical Society; First Lieutenant Medical Reserve Corps, U. S. A. Lemeke & Buechner, 32 West Twenty-seventh Street, New York City.

This little work comprises a series of monographs which have been published from time to time, now revised and collectively presented in book form. They can be especially recommended to the practical physician who wishes to familiarize himself with the most recent and approved knowledge of the diseases of the heart and blood vessels. Beginning with the more recent discoveries relating to the anatomy and physiology of the heart, he next takes up blood pressure instruments, their use, various polygraphic methods, some of the newer instruments of precision; then, in the remaining chapters, deals with some of the special diseases of the heart and vessels and their treatment, laying emphasis on measures other than drugs. While many of the illustrations are quite crude, we have no hesitation in recommending the book as one which gives, in brief space, the salient features of the present day knowledge of this special group of diseases, both from the standpoint of diagnosis and treatment.

This volume renders accessible to English readers physicians the chapter on General Paresis from Kraepelin's "Handbuch der psychiatrischen Klinik." The reviewer is indebted to Dr. W. R.Previous page of the same document. This copy is not complete and lacks visibility for any text. Subject to error until full document is visible. How fruitful this work has been attested by the present volume which is a valuable contribution to the field of clinical neurology.

Meetings of Local Medical Societies.

MONDAY, September 8th.—Society of Medical Jurisprudence: Corning Medical Association; Williamsburgh Medical Society, Brooklyn; New Rochelle Medical Society; Waterbury, Conn., Medical Association.

TUESDAY, September 9th.—Medical Society of the County of Schenectady: Medical Society of the County of Rensselaer; Buffalo Academy of Medicine; Newburgh Bay Medical Society; Jamestown Medical Society; Rome Medical Society; Practitioners' Club of Jersey City, N. J.

WEDNESDAY, September 10th.—Medical Society of the Borough of the Bronx; Brooklyn Medical and Pharmaceutical Association; Richmond County Medical Society; Dunirk and Fredonia Medical Society; Alumni Association of the Norwegian Hospital Brook-lyn.

THURSDAY, September 11th.—Gloversville and Johnstown Medical and Surgical Association; Physicians' Club of Middletown; Blackwell Medical Society of Rochester; Auburn City Medical Society; Buffalo Ophthalmological Club; Jamestown Medical Society; Society of Physicians of Canandaigua.

Official News.

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending August 27, 1913:

Ashford, F. A., Passed Assistant Surgeon. Granted one month's leave of absence from September 13, 1913.

Brown, A., Acting Assistant Surgeon. Granted thirty days' extension of annual leave of sickness, from July 2, 1913.

Clark, T., Surgeon. Directed to proceed to Upperville, Va., for the purpose of making a diagnosis of a suspected case of smallpox and for con-
BIRTHS, MARRIAGES, AND DEATHS.

Married.

Boice—Caughy.—In Baltimore, Md., on Wednesday, August 20th, Dr. Edmund Simpson Boice, of Richmond, Va., and Miss Lyla L. Caughy, of Hightown, Ohio.

Died.

Andress.—In Sparta, N. J., on Tuesday, August 26th, Dr. Theophilus H. Andress, aged seventy-two years.

Boglow.—In Albany, N. Y., on Monday, August 25th, Dr. John Milton Bigelow, Surgeon, United States Army, aged forty-five years.

Boyd.—In Goldsboro, Pa., on Thursday, August 21st, Dr. Isaac N. Boyd, aged sixty years.

Busch.—In Sandusky, Ohio, on Friday, August 22d, Dr. William H. Busch, aged forty-eight years.

Eckert.—In Fort Wayne, Ind., on Thursday, August 21st, Dr. Charles H. Eckert, aged seventy-three years.

Ewing.—In Tuckahoe, N. J., on Saturday, August 23d, Dr. Samuel Eldridge Ewing, Jr., aged thirty-five years.

Farmer.—In Fairmount, Ky., on Saturday, August 23d, Dr. Thomas A. Farmer, Surgeon, United States Army, aged sixty-seven years.

Fitch.—In Augusta, Me., on Thursday, August 21st, Dr. Calvin Huntley Fitch, aged eighty-four years.

Foster.—In Kansas City, Mo., on Wednesday, August 20th, Dr. George E. Foster, of Springfield, Mass., aged sixty-five years.

Hunter.—In Leechburg, Pa., on Wednesday, August 13th, Dr. Robert P. Hunter, aged seventy-three years.

Jordan.—In Wichita, Kansas, on Tuesday, August 13th, Dr. William A. Jordan, aged sixty-seven years.

Lee.—In Easton, Pa., on Monday, August 25th, Dr. Alfred H. Lee, aged seventy-three years.

McCarthy.—In Brockton, Mass., on Friday, August 23d, Dr. William Henry McCarthy, aged forty-six years.

Mayer.—In San Antonio, Texas, on Monday, August 18th, Dr. Augustus Maverick, aged thirty-seven years.

Meyer.—In Rochester, N. Y., on Sunday, August 24th, Dr. Sidney A. Meyer, aged sixty-six years.

Ray.—In Los Angeles, Cal., on Tuesday, August 13th, Dr. Charles Wilbur Ray, aged fifty years.

Rutledge.—In Kansas City, Mo., on Wednesday, August 27th, Dr. Charles H. Reinsberg, aged forty-six years.

Shay.—In Marlborough, N. Y., on Thursday, August 21st, Dr. Daniel Aloysius Shay, of Brooklyn, N. Y., aged thirty-seven years.

Treadwell.—In Portsmouth, N. H., on Saturday, August 23d, Dr. Robert O. Treadwell, aged eighty years.

Walton.—In Mulga, Ala., on Monday, August 18th, Dr. Frank Walton, aged thirty-eight years.

Williams.—In Richmond, Va., on Wednesday, August 20th, Dr. James Porter Williams, aged forty years.
Original Communications.

DISCARDED BATTLESHIPS TO BE USED AS SANATORIA AND OPEN AIR SCHOOLS.

Preliminary Remarks and Resolutions on the Use of Discarded Battleships for Sanatoria, Preventoria, and Open Air Schools, Offered to the Fourth International Congress on School Hygiene in Buffalo.

N. Y., August, 1913.*

BY S. ADOLPHUS KNOPP, M. D.,
New York,
Professor of Medicine, Department of Phthisiology, at the New York Post-Graduate Medical School and Hospital.

I desire to bring before the congress at this time some resolutions regarding the utilization of our discarded battleships for open air schools, preventoria, and sanatoria for tuberculous children and adults. I include the adults because if we cure the parents from this disease we will not have to treat as many of our school children for the same affliction.

Before an audience of this kind it is unnecessary to emphasize the well known fact that there is hardly a community in these United States which has sufficient sanatorium and hospital facilities to take care of its tuberculous adults and children. But since this congress is particularly interested in the child, I wish merely to call attention to the fact that of the 20,000,000 pupils now attending American public schools at least five per cent. are tuberculous or so strongly predisposed to the disease that they should be immediately taken out of school and placed in special open air sanatoria, schools, classes, or preventoria. Carefully gathered statistics show that we provide open air instruction at this time throughout the entire country for scarcely more than 1500 pupils, and yet, as stated on another occasion,1 if we wish to prevent tuberculosis in children the open air school must become the rule, the indoor school the exception.

According to the following list of obsolete ships and their original cost, the United States govern-

*The remarks and resolutions were first presented at the close of a Symposium on Tuberculosis, arranged for the congress by Doctor Farrand, the executive secretary of the National Association for the Study and Prevention of Tuberculosis, and president by its president, Dr. John H. Lowman. In accordance with the rules of the congress these resolutions were referred to the Committee on Resolutions. They were approved by the latter and passed unanimously without discussion at the final general meeting of the congress, August 29, 1913, President Charles W. Eliot in the chair.

ment has expended nearly $130,000,000 for the construction and equipments of these vessels in less than twenty years' time:

</table>

Now, these ships have done their service. We have since built new ones and are building new ones at this moment. As representatives of all nations united here for the most peaceful purpose of all, the preservation of childhood, we pray that these new battleships, cruisers, and monitors may never go into action. In any case, in due time they will be discarded also. What I am pleading for to-day is that a good use be made of these discarded men of war. I would make them into life saving instruments, the very reverse of that for which they were created. These discarded battleships should not be turned into junk. They can be transformed into all year round sanatoria and open air schools with relatively little expense. If put to the use I suggest, they can still be considered nominally as units of a reserve fleet, but our hope is that there may never be any need of their use as such.

In a recent communication to the public press on this subject, Dr. Arthur C. Jacobson, of Brooklyn, pleading for the same cause, called attention to the fact that the secretary of the Italian navy recently...
had decided to convert three of the old Italian warships into sanatoria for tuberculous children, and Doctor Jacobson very justly adds: "Why would it not be possible for the United States government to emulate the example of the progressive Italian statesman?"

I communicated recently with the head of our own government, President of the United States, the Hon. Woodrow Wilson, concerning the utilization of discarded battleships for open air schools and sanatoria for the tuberculous. He very cordially instructed his secretary to reply to me, saying that the matter would be brought to the attention of the Secretary of the navy. The proposition has the strongest approval of the president of our National Association for the Study and Prevention of Tuberculosis, Dr. John H. Lowman, professor of the Western Reserve University of Cleveland, Ohio, and also of our secretary general of this congress, Dr. Thomas A. Storey, professor of Hygiene of the College of the City of New York.

Before deciding on this important action I went for advice and counsel, as I have done so often before in my professional life, to my venerable teacher and friend, Professor A. Jacob, former president of the American Medical Association, and the Nestor of the American medical profession. He heartily approved of the scheme and urged me to present these resolutions. My friend, Dr. John H. Hudleston, the director of the Gouverneur Hospital Tuberculosis Clinic and the physician to the Tuberculosis Service on the ferryboat anchored near that hospital, writes me enthusiastically about the splendid results obtained in the boat service, which he considers one of the most valuable adjuvants to our antituberculosis institutions of the city of New York.

Doctor Jacobson, whom I mentioned before, is the examining physician of all applicants for the preventoria, sanatoria, and hospitals for the tuberculous of Brooklyn. After telling him of my intention to bring this matter before this congress he wrote me enthusiastically about it, saying: "If we could permanently moor a battleship in the roadstead of Staten Island, and then use smaller craft for ferriage and excursions 'round about the sound and elsewhere, then we would not have that long waiting list for the preventoria at Farmingdale and Nanuet. If the government could not give such a craft away, a doubtless a safe could be arranged with a sympathetic navy department."

Mr. Frank H. Mann, the secretary of the committee on the Prevention of Tuberculosis of the Charity Organization Society of the City of New York, when he heard of my intention to bring this matter before the congress, wrote:

I am much interested in your plan of presenting a resolution at the Fourth International Congress on School Hygiene, calling upon the government of the United States and other countries to make use of their abandoned war vessels for the purpose of open air schools and hospital sanatoria. As you probably know, the first day camp in this city was opened by this committee in 1906 on an old ferryboat loaned by the Department of Docks and Ferries. The use of the boat proved so successful that other boats have been pressed into service. With the exception of the Vanderbilt Clinic Day Camp, which is held on the roof of their building, all of the day camps in New York city are conducted on ferryboats. These camps are operated both summer and winter, with best results in winter per-
prevention of tuberculosis in the predisposed and the cure of the afflicted; and
Whereas, Statistics show that there are not nearly enough hospital and sanatorium accommodations for adults and children afflicted with pulmonary tuberculosis or children suffering with tuberculous joint or bone diseases; and
Whereas, It has been demonstrated in New York and other cities that discarded vessels lend themselves admirably to transformation into all year around hospitals and sanatoria for consumptive adults, sanatoria for children afflicted with joint and other types of tuberculosis, and into open air schools for tuberculous, anemic, and nervous children.

Resolved, That the Fourth International Congress on School Hygiene petitions the United States government to place at the disposal of the various States of the Union as many of the discarded battleships and cruisers as possible to be anchored according to their size in rivers, or at the seashore, and to be utilized by the respective communities for open air schools, preventoria, sanatorium schools for children, or hospital sanatoria for adults. Be it further
Resolved, That the congress expresses its appreciation to the Italian government for the example it has given by consecrating three of its discarded men of war to the combat of tuberculosis. Be it further
Resolved, That this congress expresses the sincere wish that other governments may follow the example of Italy; and be it finally
Resolved, That copies of these resolutions be presented to the American and other governments represented at this congress.

16 West Ninety-fifth Street.

THE RELATIVE VALUE OF TURTLE TUBERCULIN IN THE TREATMENT OF TUBERCULOSIS.

By William J. Beattie, M.D.,
Littleton, N. H.* Formerly Assistant to Professor Piorkowski in Berlin.

AND EDWARD E. MYERS, M.D.,
New York, Assistant Laryngologist and Rhinologist to Outpatient Department, New York Polyclinic School and Hospital; and Assistant Laryngologist to the Vanderbilt Clinic, Columbia University.

The history of medicine is accentuated by progress. In glancing over its pages the student is astonished at the rapid strides and wonderful discoveries made to alleviate human suffering. New operations, improved surgical technic, and new therapeutic remedies have been the means of giving suffering humanity new leases on life. One of the most notable discoveries in the history of medicine was the introduction of vaccine against smallpox. Other wonderful lifesaving discoveries have been made by Lister, O'Dwyer, Morton, Long, Ehrlich, von Behring, Koch, von Ruck, and others.

Progress along all lines of medical endeavor, as well as all epoch making discoveries in the field of medicine for the relief of diseased humanity, have been hindered by the ultraconservatism of the medical profession. The discovery of vaccination was pooh poohed by the London profession, who bitterly attacked Jenner, the discoverer, and when compelled, acknowledged its lifesaving virtues and abandoned professional skepticism. All new methods and measures—all new drugs and discoveries ought to, and should hold the attention, and command the cooperation of every thoughtful, earnest, honest physician, who must forsake his ultraconservatism and pay due homage to the newer discoveries, especially specific serum and vaccine therapy, which while only in its embryonic stage, as it were, have contributed to the amelioration of the ills of mankind.

The treatment of individual diseases with medicines, or by methods having a selective curative action, has until recent years been limited. With the establishment of the germ therapy of certain diseases and the development of information concerning immunity, new methods of specific treatment have been made possible, and are now practised under the terms serum and vaccine therapy. Its development has been slow, the methods have undergone revision from time to time, and in some cases results have been disappointing. Because of this much confusion has arisen concerning serum and vaccine therapy.

To Robert Koch belongs the honor of giving to the world tuberculin twenty-three years ago. This was the first great advance in the diagnosis of tuberculosis. Prior to this the disease was generally recognized as a fatal malady; it was not diagnosed until the symptoms were marked and then death was required to substantiate the diagnosis. Koch has been blamed for many things for which he was not responsible. He was utterly helpless in controlling the early administration of his tuberculin or in having it administered in strict accordance with his ideas, but it is an indisputable fact that he had a grasp of this new subject which was truly marvelous. It must be remembered that nothing like tuberculin had ever been produced before. He was tilling virgin soil with nothing as a precedent to guide him, except his own broad comprehension of scientific principles, especially those of bacteriology. That he did not understand fully the action of tuberculin is not to be wondered at, and his errors of doses should not be held against him. Had he been able to transfer his grasp upon the subject, in all its details, to clinicians who followed in his wake, no doubt the early disaster of its being vaunted as a long looked for specific would have been avoided. His discovery of the differences in the action of this remedy on the healthy and tuberculous, has proved to be one of the most important discoveries in the modern study of tuberculosis. It has given us the tuberculin test, which not only makes possible an early diagnosis of the presence of tuberculosis, but also has given us a more thorough understanding of the nature of the disease and the essentials of its prevention, as well as, led to its specific treatment. His descriptions of the symptoms of reaction are accurate and complete.

The tuberculin treatment, sternly rejected after its unsuccessful introduction by Koch, has again become extremely popular. A voluminous literature has sprung up, and until recently there was much uncertainty as to its real therapeutic value, but recent developments in biology and bacteriology by von Behring, Bordet, Wright, Wassermann, von Ruck, Calmette, and Piorkowski have cleared away the mists of uncertainty sufficiently, to permit us to take our bearings for a practical course. During the past decade the use of tuberculin as a diagnostic and curative agent has received considerable atten-
tion. The new methods of application in diagnosis, brought out by earnest investigators, have stimulated a desire on the part of the profession to determine their value, and recent changes in their attitude, toward important questions bearing upon immunity, have provoked extensive researches, undertaken to make clear its mode of action.

The most earnest investigator along these lines, in our own country is Dr. Karl von Ruck, a learned scientist, of Asheville, N. C., who for the past twenty years has devoted his time and energies to the clinical, biological, and bacteriological study of vaccine therapy. He has administered human tuberculin in many thousand cases and summing up the subject says: "Products derived from human tubercle bacilli, in the form of tuberculins and emulsions of their bodies, have been in the hands of the profession for more than twenty years, and in hundreds of thousands of cases of tuberculosis they have been employed with more or less success, and not infrequently with failures, while occasional detrimental effects have been ascribed to their action."

Von Ruck referring to Dr. Franz F. Friedmann's claim of the superior value of living tubercle bacilli in the treatment of tuberculosis, and his spectacular advertising propaganda in the daily press, says: "Inasmuch as living tubercle bacilli of the human type have been found in vaccinated cattle, both in their flesh and in their milk, as long as three years after their intravenous injection, the objection to the use of the living tubercle bacilli as an antigen, or vaccine, for prophylactic purposes in the human subject is well founded." A more formidable objection is, however, the danger of virulence. That this can occur in the case of tubercle bacilli, the same as of other pathogenic bacteria, is a well known pathological fact.

Max Piorkowski, working along the lines of Koch's discovery, isolated a living antigen in the form of tubercle bacilli recovered from a turtle, as far back as 1903, without in any manner questioning their nonvirulence. Since that time he has continued his researches on this subject in his well appointed biological and bacteriological laboratories in Berlin, and has at last succeeded in perfecting a tuberculin, produced from the tubercle bacilli of a cold blooded animal—a certain species of turtle—which is nonvirulent, and with which he has successfully experimented in hundreds of cases during the past two years at his laboratory in Berlin. It was from Piorkowski's laboratories that Dr. Franz F. Friedmann learned of the former's work of isolating a living antigen from the tubercle bacilli recovered from turtle serum, and it was these living turtle tubercle bacilli which Friedmann used, thinking he had Piorkowski's nonvirulent turtle tuberculin. In this he was mistaken. In the light of the present it remains for Friedmann to show "that his particular culture is permanently avirulent for the human subject, which he has not done, and which he is unable to do, because he has the living antigen in the form of tubercle bacilli from turtle serum." (von Ruck—Journal of the American Medical Association, 1913.)

Piorkowski, in a lecture delivered at the Royal Hospital for the Diseases of the Chest, London, England, on April 1, 1913,1 on referring to his turtle tuberculin, says: "We must differentiate between mammals which produce their offspring alive, the class to which human beings and oxen belong, and birds, i. e., that is, animals which lay eggs; and, thirdly, reptiles, which possess horny or long integument and also lay eggs. Lizards, crocodiles, and turtles belong to that last class. Finally, we have to think of fish which breathe, as long as they are young, through gills or by their lungs, and also lay eggs. We thus see very clearly that resemblances are to be found only among lung breathing animals, and it is for this reason, probably, that the results described are obtained on the injection of tubercle bacilli of similar kind. It became very evident that turtles were especially adapted for our purpose."

He further states that in 1901 two large turtles were brought to his laboratory which had become spontaneously tuberculous, their lungs containing a large number of tuberculous nodules from which he made pure cultures on suitable nutrient media. His experiments with turtles extended over many months, and he finally concluded that he was dealing with a special strain of bacilli which, when developed on a specially prepared nutrient medium, exhibited the symptoms of tuberculosis. In further describing his work along this line he says: "It is very noteworthy that the turtle tubercle bacillus in its further behavior, both culturally and morphologically, displayed an extraordinary resemblance to the human tubercle bacillus. Its growth at 37° F. is remarkably characteristic. The main point about this strain is that it can be used without the risk of any manifestations—a circumstance which may be ascribed to the fact that for the last ten years it has been reinoculated afresh daily, and thus has acquired generally an extraordinary innocuousness, becoming both avirulent and atoxic."

He explains the differentiation of the various tubercle bacilli by citing Knoll's modification of Unch's method, which consists of a double stain by means of fuchsin, methyl violet, and resorcin, and concludes "this method reveals long slender structures with regular nuclei in human tubercle bacilli, but in this variety the nuclei are often seen to be irregularly divided and of a variable size. In avian tubercle bacilli, they are somewhat shorter, and in turtle bacilli they are very small—almost like dots. In my opinion the extraordinary resemblance of the various tubercle bacilli is to be attributed to the zoological grouping, and such resemblances only occur in lung breathing animals."

The method of working with living bacilli is by no means new to pathologists. Piorkowski and von Ruck both used this same principle years ago, and von Behring used it in his experiments when attempting the extermination of bovine tuberculosis. He used human tubercle bacilli, which are atoxic to cattle, with good results. Reasoning on this anology, Piorkowski believes the use of turtle tuberculin in human beings, as a curative and immunizing agent, is quite rational. He explains its biological action very satisfactorily by citing Führich's side chain theory of immunity. According

1British Journal of Tuberculosis, July, 1913.
to this theory every living cell consists of a dominating nucleolus and of side chains, or receptors. The side chains or receptors of a cell are of many different kinds, and, usually serve to anchor food-stuffs. When nutrition reaches the cells by this method—through the receptors—a most remarkable biological phenomenon occurs, according to Piorkowski, in the following way: "The portion of the cell which has absorbed the nutrient breaks away from the rest, becomes metabolized, and a new receptor is developed in the original cell; but not merely one receptor—an actual outgrowth of receptors takes place (Weigert's law of overcompensation). The new receptors having been charged with nutritive material, break away, and carry the nutrition to different parts of the organism, thus effecting nutrition." This theory not only accounts for the method of nutrition, but it also explains how toxic action occurs; because cells not only possess receptors for food molecules, but also for other substances, and these receptors are as numerous as they are varied. Some of them take up particles of nutrition, others take up poisons and absorb ferments, while others are the products of bacterial fermentation or similar processes.

It will be understood that the principal function of all receptors and side chains is to provide for the nutrition and metabolism of the cells. Receptors, and hence immune bodies, however, are not of the same general structure. In order to explain the different functions and actions of different immune bodies, Ehrlich assumes that the receptors may be of simple constitution and structure or they may be complex. Any cell of the body may have large numbers of the same and different kinds of receptors, which he divides into three orders: Receptors of the first order are of relatively simple constitution and structure and combine with substances that are easily and readily anchored, such as bacterial toxines. The receptor here consists of only one haptophile or combining group, which combines directly with the haptophile group of the bacterial toxine. This order of receptors and immune bodies represents the type of receptor on which is based the action of bacterial toxine and the formation of antitoxine.

Receptors of the second order are distinguished from those of the first by the fact that the receptors here have in addition to the haptophile group a zymophile group, which latter group acts on the larger food particles, making them more readily and easily assimilable. In a similar manner it also acts on the bacterial cells. Schorer² teaches that "receptors of this kind, possessing both haptophile and zymophile groups, are broken off from the cells and circulate in the blood as agglutinins and precipitins after immunization by the injection of certain bacteria. The haptophile group of the immune body in an agglutinating or precipitating serum combines with the bacterial cells. The zymophile group, however, does not combine with anything, but exerts its influences entirely through the haptophile group. The zymophile group is destroyed by age, acids, heating to 65° C., etc."

Receptors of the third order are likewise adapted to the anchorage of bacteria. "These receptors, however, have two combining groups: one for the anchorage of cells for the reception of nutrition and the other for the anchorage of substances which, acting through the receptors, can produce a fermentlike action. This latter substance is called an activating substance, which is present in normal sera and is known either as complement or alexin."

Schorer commenting on Ehrlich's side chain theory of immunity avers: "When receptors of this order are anchored by bacteria in numbers not sufficient to kill the cell, but to stimulate it to overproduction of receptors, the extra receptors are thrown off. The receptors thrown off constitute the immune body, amboceptor, or substance sensibilitrice of Bordet. They have two combining or haptophile groups, one for the combination with bacterial or other cells and substances, called the "cytophilic" group; the other for combination with alexin or complement, called the "complementophore" group. It is by means of complement, that the amboceptor is able to dissolve bacteria, red blood cells, and other substances. Immune sera containing receptors of the third order are, bacteriolytic, hemolytic, or cystolytic, depending upon whether they, together with complement, can dissolve bacteria, red blood cells, or other cells."

It is enunciated by Ehrlich's side chain theory that receptors of the first, second, and third orders can be produced in excess to form immune bodies or antibodies. "Specific immune bodies are produced from a variety of substances, toxines, bacterial cells, red blood corpuscles, ferments, etc. On account of the multiplicity of substances which the cells may use to produce antibodies, antibodies may be antitoxic, agglutinating, precipitating, lytic, etc." Schorer believes that in order to produce agglutination, precipitation, or lysis it is necessary that a fermentlike substance be a part of, or able to combine with, the immune body. This fermentlike substance, as stated before, is labile and lost through age, heat, etc. When this is lost the serum containing the immune body is said to be inactive. Piorkowski, in explaining Ehrlich's side chain theory, says:

Let us, for example, consider a toxic action a little more closely. When a poison enters the body, e.g., tubercle toxine, the first point concerns the existence of receptors which can take up the tuberculous poison. If these do not exist, no infection by tubercle bacilli can occur, for the organism possesses congenital immunity toward the action of these bacilli. But if there be some arrangement for receiving them, and appropriate receptors for the tubercle bacilli exist, these take up the poison, and if absorbed in sufficient quantity, a general toxemia ensues, which may lead to the destruction of the organism. If, however, the receptors have the opportunity of loading themselves with the poison, and if they drop off the cell after they have become useless and harmless, then an excessive production of these receptors occurs, and stated previously. A constant succession of new receptors become formed; but if there is not room enough on one cell for the attachment of so many receptors, and the result is that the newly formed elements become discharged into the serum before they have been able to take up any of the toxic material, the receptors thus discharged come into contact with poison in regions far distant from the site of the sensitive cells, and are there seized upon, whereby a ventilation of the poison takes place and it is rendered injurious. In this manner an acquired specific
immunity is developed, and the newly formed bodies are termed "antitoxines."

The harmless turtle tuberculous toxin combines with the receptors, and the combination is thrown off into the blood as antitoxine. Now, receptors are formed in large quantity, but they are capable of seizing not only the turtle tubercle bacillus, with which they have been hitherto dealing, but also human bacilli, and thus render them harmless. If there is a profuse formation of new receptors, and if the human tubercle bacilli have increased unduly, complete recovery may be effected. The rationale of the cure is along these lines. There is also the additional advantage that turtle tubercle bacilli are innocuous and harmless, and therefore this method is especially well adapted for protective inoculation. But even if the body is already affected with tuberculosis the disease can be suppressed, because its course is so protracted.

The process is very much the same as that of Jenner's vaccination against smallpox, except that in the latter case the agent is calf lymph, whereas here it is the turtle tubercle bacillus. All the endeavors in the therapeutic of tuberculosis based upon Koch's work, which consist of injections of living tubercle bacilli or the virus, attain a certain result, but, if accurately judged, fail to reach their ultimate aim. In order to attain this end it is necessary that the antigen which is to invoke the protective and curative powers of the body should be alive, but deprived of the poisonous properties—avirulent and atoxic. It is, further, necessary that the tubercle bacillus which is concerned in this matter should be treated as carefully as possible, and should be both active and specific. To a very considerable extent these desiderata have been arrived at in my laboratories.

Recent investigations with turtle tuberculin, in Piorkowski's laboratory, made by Dr. W. J. Beattie, of Littleton, New Hampshire, have shown that tubercle bacilli, when grown in the blood serum of turtles (cold blooded animals), change quite distinctively its bacteriological characteristics, particularly in lessening its virulence and at the same time increasing its power to form antibodies in the blood of tuberculous patients. This turtle tuberculin acts as a direct stimulant to the antibodies of tuberculosis exerting far greater beneficent effects than human tuberculin, even when the latter is given in the most carefully guarded and graded doses. Furthermore, turkey tuberculin produces only a very slight reaction, besides it possesses far greater immunizing properties than does human tuberculin with none of the latter's untoward effects.

Turtle tuberculin is a clear port wine, reddish, brown liquid containing the products of the tubercule bacillus of a certain species of turtle.

Dose.—Piorkowski's turtle tuberculin is prepared like Koch's; but no temperature higher than 35° C. in vacuo is employed in its preparation. Piorkowski lays down the following directions for estimating the dose: "The administration should be intramuscular, but it may also be given subcutaneously, or intravenously. The turkey tuberculin in doses of 0.1, 0.3, and 1.0 c.c., according to the stage of the disease and the temperature—in other words, according to the clinical condition. It is best to begin with 1.0 c.c. of the tuberculin, after another eight days repeating the latter injection at frequent (weekly) intervals. Numerous experiments on animals and the treatment of a large number of cases have confirmed the absence of any toxic effects. Owing to the careful methods of preparation of this remedy, there have hitherto been no instances of induration or abscess; there have only been slight infiltrations which subsided very satisfactorily. The most striking clinical results have been the rapid subsidence of fever, night sweats, pain in the chest, and other pains. Very soon there is an increase in weight, appetite returns, and the feeling of fatigue disappears."

By repeated injections, personally made by Doctor Myers in fifty odd cases and observation on about one hundred and twenty-five patients injected by Doctor Beattie, the smallest immunizing dose was one minim of turtle tuberculin administered in sixteen maxims of normal salt solution. The interval between doses depends upon the recurrence or exacerbation of the original symptoms; it is usually about seven days. Very slight reactions such as a rise of temperature to 100° F., and more or less languor for about twenty-four hours following the injection, are the only reactions which occur even with a maximum dose. These slight reactions are desirable because all study of tuberculin therapy shows that a slight reaction is the indication of the reactive process produced about the lesion.

Site of injection.—The best site for the injection of turtle tuberculin is in the fold of the gluteal region between the gluteus maximus and minimus muscles which location will facilitate its rapid absorption.

Contraindications.—Advanced types of pulmonary tuberculosis, and morbid cases of all types do not hold out the encouraging possibilities for cure that the first and second stages do.

Choice of patients.—The most suitable cases are the incipient pulmonary, glandular, laryngeal, and joint cases.

Local reaction.

Human Tuberculin
Redness and infiltration begin in area of injection in from four to eight hours. No thickening of skin. Area of infiltration usually very tender. Abscess sometimes follows injection. Abscess, lymph glands swollen.

Comparisons between human and turtle tuberculin.

Human Tuberculin

Comparisons between turtle tuberculin.

Turtle Tuberculin
Dose greater. Effect more rapid. Reaction slight. Length of treatment short.

Hygienic
Not always feasible. Treatment prolonged. Necessitating interference with daily avocation. Results not always satisfactory. Recurrence frequent.

Turtle Tuberculin
Always feasible. Treatment shortened. Does not interfere with daily avocation. Results very encouraging. Recurrence improbable.

Constitutional effects.—About twelve hours after the injection the patient experiences a feeling of lassitude and languor, the temperature rise from 90° to 100° F.; the appetite diminishes, but at the end of twenty-four hours the patient feels a well as before the injection.

Effects in glandular cases.—The most striking
beneficial effects of turtle tuberculin is observed in glandular tuberculosis or scrofula. Improvement is noticed after three weekly injections have been made. The glands gradually become smaller and, where there is a discharging sinus, the secretion progressively diminishes, the opening becomes smaller and the sinus finally closes up, and the temperature gradually returns to normal. The patient gains in weight, his appetite improves, and a feeling of buoyancy replaces that of languor and lassitude.

Effects on joint tuberculosis.—After about four weeks there is a noticeable diminution of the swelling about the joints, the pain is diminished or disappears, and the amount of motion is increased from five to ten degrees. The patient gains in weight; the temperature declines; the appetite improves; and the patient notices a feeling of buoyancy and strength, and follows usual avocation without unusual fatigue.

Effects on pulmonary tuberculosis.—About six weeks after beginning treatment the patient's general condition improves. His cough becomes less, and his sputum diminishes and becomes more mucoid in character. The pains in the chest disappear; the night sweats become lessened and gradually disappear.

Objective signs. If a patient has a localized bronchitis the signs in the lungs gradually become changed, and the râles gradually disappear. Where the patient has an area of consolidation, the area is occasionally noticed about the end of the eighth week.

Effects on laryngeal tuberculosis.—In laryngeal tuberculosis the ulcerations slowly but progressively dimish and soon heal. The inflations become lessened, the mucous membrane assumes its normal color, and the pain on swallowing and hoarseness become markedly diminished and entirely disappear at the end of (about) eight weeks.

Duration of treatment.—The treatment is usually continued until all objective and subjective symptoms disappear, which is generally in from six to nine months. The duration of the course varies with the stage of the disease and the type of the case. Glandular and joint cases usually respond in six months.

That the effects produced are due to the direct action of the tuberculin and not to any mental suggestion have been proved by the beneficial results obtained in children too young to be influenced by mental suggestion.

To prove that turtle tuberculin is the cause of the beneficial effects produced, patients treated can be shown where pleasing results have been obtained in cases in which other methods of treatment have completely failed.

ROBINSON: HYGIENE OF THE SKIN.

HYGIENE OF THE SKIN.

By Daisy Orleman Robinson, M. D.

New York.

The structures composing the skin consist of several forms of tissues arranged in a complex manner to fulfill the physiological actions pertaining to this part of the human body. The skin is not only a protection against external injurious conditions, but it has functions to perform in the life activities of the organism as a whole, exercising the following one or more protect the subjacent tissues. Heat regulation, tactile and thermal sensation, respiration, secretion, and elimination. It has its anatomy, its physiology, its pathology, its different characters in different races, and its peculiarities in different men, women, and children, and it varies in thickness, color, quality and sensibility. It has its epidermis, with its special developments, the hair and nails; it has its bloodvessels, its lymphatics, its nerves of various kinds, and its connective tissue.

Since the hygiene of the skin consists in keeping the structures in a normal condition of nutrition, in order that their physiological functions may be performed in a proper manner, it will be necessary first to state briefly the anatomical structure of the skin: then to consider the conditions of the general system that contribute to the normal activity of this part of the body, and those that interfere with its normal structure and physiological action; and, lastly, to mention the various kinds of external agents that can act injuriously, their method of action, and the best means of protection against them. The latter will receive some attention, as it is assumed that most interest is attached to the hygiene of the skin in reference to external measures, such as the use of powders, soaps, ointments, baths, etc.

For a more direct comprehension of the skin, we must first examine into its anatomical characteristics. The skin is divided into two layers, the epidermis proper or external layer, and the cutis, or so called true skin, lying beneath. Both layers are further subdivided—the epidermis into four; corneous layer, stratum lucidum, granular layer, and rete mucosum; the cutis into three—papillary layer, corium, and subcutaneous layer. The corneal layer of the epidermis is composed of so called horny cells, which undergo a peculiar transformation in their chemical structure in passing from the lower layers to the free surface of the body. They may be regarded as

418 CENTRAL PARK WEST.
cells undergoing degeneration, or, rather, a process of death—to be finally cast off when they reach the surface. This casting off, or separation from the body, is a continuous process, varying in degree under different conditions. From the character and arrangement of the cells, it acts as a protection, forming a firm, closely attached cell membrane. As it is free of bloodvessels and lymph channels, it protects the body, when in a normal condition, against the invasion of many pathogenic or disease-producing organisms. It is only when from some cause, such as an injury producing a break in this tissue, a cut with a sharp instrument, or an abrasion from scratching, etc., that the deeper tissues are reached, and disease processes thus started. It is on account of such breaks in the epidermis, in the form of cracks or raw surfaces, that so many physicians, for instance, become infected by a serious blood disease in the treatment of patients in whom the disease microbe exists. It is known that such a disease cannot be contracted when the epidermis is absolutely intact. This knowledge is utilized in the operation for vaccination; the corneous layer is injured or partly removed in order that the vaccine may reach the deeper living tissue, for instance, the rete, from whence the microbes can pass into the system and produce the disease vaccinia, which protects against smallpox. The importance of all this shows the necessity of keeping the corneous layer in a normal condition. The thickness of this layer varies in different parts of the body, being thickest on the palms of the hands and the soles of the feet, where it also acts specially against mechanical injury to the deeper tissues, as in walking and in many kinds of handwork. The shafts of the hair and the nails are almost entirely composed of these horny cells.

The next two layers, the stratum lucidum and the granular layer, representing stages of transition from the rete to the corneous layer, need on this occasion no special description, although in many disease conditions they are subject to variations in character, especially the granular layer. For instance, in warts it is increased in thickness. The next layer, the rete mucosem (lower layer of the epidermis) is composed of living cells, united to each other by so-called spines between the cells with intercellular spaces, through which nourishment is furnished from the underlying tissues. Owing to the character of this structure, substances can be absorbed from without, whether applied in the form of ointment, powders, or solutions. The lowest layer of cells is called the germinal layer, because all the other cells of the entire epidermis are formed from it, and the majority of cutaneous cancers arise from these rete cells. It is the rete layer that is especially affected in many of the inflammatory affections of the skin, such as eczema. It is in the lower layers of the cells of the rete that the pigment is contained, the color and quantity of which influence the color of the skin. This pigmentation is very marked in the colored races as compared with the white races. In certain instances it becomes so excessive in amount as to constitute a condition which has been classified as a disease, namely, that so frequently observed as brownish patches on the faces of women. These are incorrectly called by the lathy, liver spots. This increased pigmentation may be considered as the result of an abnormal condition in the system, probably the genital system, and not from the liver. From the deep seated location of these pigmented cells, the uselessness of attempting the removal of this condition by external applications is evident, although beauty specialists advertise their secret methods as being able to accomplish this impossible feat.

The structures just described are composed of epithelial cells, the kind of structure that forms all the secreting organs of the body and lines all mucous membranes—that of the respiratory channel from the nasal openings to the air cells of the lungs, and of the digestive tract from the lips to the end of the intestinal canal. In the skin there are specially changed and arranged epithelial cells to form secreting structures called glands, with special physiological functions to perform, such as the hair follicles, the sebaceous or oil producing glands, and the sweat glands. As a normal condition of these glands plays a part in the maintenance of the health of the body in general, and of the epidermis in particular, especially of the corneous layer, I shall briefly consider their functions, and how they may be preserved, or interfered with to the injury of the skin, thus taking part in the causation of some of the most frequent diseases of the skin. A sebaceous gland consists of the secreting portion of the gland proper and the duct, containing the sebum, an oily substance which oils the hair and to some extent the corneous layer of the skin. If the functions of these glands are impaired, the result is a dry and scaly skin, or it is covered with a greasy liquid, which may lead to loss of hair. An example of interference with the normal action of the sebaceous glands is afforded when there is an excessive production of sebaceous gland cells, whether caused by microbes or not, or when there is an obstruction to the passage of the oily material to the free surface resulting in the formation of a plug, the so-called fleshworm. It is this plug which forms the habitat for the organisms or the microbes concerned in the production of acne, or, as it is usually termed, pimples, seen on the faces of young persons. The maintenance of the glands in a normal condition by suitable local hygienic measures is the best means for the prevention of this condition.

The sweat glands are situated deep in the corium and subcutaneous tissue, having tubes twisted upon themselves in the shape of a coil and long excretory ducts which open upon the surface of the skin, and it is these microscopic mouths that are ordinarily called pores of the skin. The object of the sweat secretion is the regulation of the body temperature by the elimination of water. This cutaneous respiration plays an important part in the purity of the blood. The odor of perspiration varies with the race and with the individual, and in different parts of the same person. Decomposition of fat into the fatty acids is the usual cause of the odor perceptible in many persons, and is most marked in those parts of the body where there is a large amount of fat secreted, as in the arm pits. In the disorder of the sweat glands known as bromidrosis, the sweat has a markedly offensive odor.
The hair has its origin in the hair papilla, situated at the bottom of the hair follicles; and these papilla are found at different depths of the skin in different parts of the body; being deepest where the hairs are most developed. The hair of the human subject is not shed at definite periods, as in many of the lower animals, but there is a constant falling of the hair and a replacement by new hairs. Sometimes a large number of hairs fall out within a short period, leaving persons to believe that they are about to lose their hair, but, unless this is associated with some local or general disease, they may be assured that new hair will take the place of the lost hair. The growing gray may be either premature or a normal physiological process. Some instances of premature grayness depend upon heredity, in which case it may be considered a physiological process and beyond treatment. Other cases may follow some of the infectious diseases, as typhoid fever, or may result from neuralgia or psychic shocks. The physiological senile grayness admits of no treatment beyond that of general hygiene and rest. The view that hair can become definite in a single night, whether from sudden fears or otherwise, has lately been questioned by some writers. The prevention of the falling out of the hair in consequence of conditions such as dandruff, the most frequent cause of premature baldness, depends upon the success of measures for the prevention of the causative condition. If the changes in the skin in cases of dandruff have extended below the neck of the hair follicle, a restoration to a normal growth may be considered as beyond our present measures of treatment. All preparations advertised or recommended to produce a normal growth of hair in cases of baldness, secondary to a long standing dandruff, are absolutely worthless. A cranium which has only very small fine hairs, few in number, irregularly distributed, and associated with a shining surface, is beyond the stage for successful treatment. Where the hair falls out originally in roundish spots without signs of inflammation or scaling, even though the whole scalp be affected later, it can, as a rule, be quickly cured by active and correct treatment, which should be directed by an expert physician. Hygiene of the skin has nothing to do with this form of disease. Dying of the hair, when the application is confined to the hair shaft, does not injure the skin, but some hair dyes, if applied to the scalp, may produce a severe inflammation of the skin in some persons. In such cases some preparation of different chemical constitution should be employed. The fault in these cases is not necessarily with the character of the dye, but lies rather in the susceptibility of the individual, and is certainly not a just claim for damages from a hairdresser.

Hypertrichosis, or hirsuties, which is an abnormal growth of hair upon any part of the body, is a condition for which treatment is frequently requested. When this increase is situated upon the face, for instance, sufficiently to cause a marked deformity, the hairs, if not too numerous, may be removed by electrolysis or other means. The use of depilatories has a tendency in time to stimulate the growth, on account of the irritation resulting from the application causing increased blood supply to the part. It is probable that the growth of hair sometimes observed after the use of cosmetics of an oily nature, as cold cream, hydrous wool fat, or petrolatum preparations, is due more to the increased blood supply brought to the parts from the application than from the supplying of any special food substance to the hair directly. In any case, it is not advisable to make use of these preparations on the skin if avoidable. In those unusual cases where there is a marked increase in the growth of the hair on the face or some other part of the body during pregnancy, the hair after parturition has a tendency after a time to return to its normal condition. The growth, no doubt, depends upon some substance, a hormone, possibly present in the system at that period. The frequency in the washing of the hair depends largely upon the condition of the scalp—in other words, it is merely a question of cleanliness. No soap should be used that injures the scalp. As a rule, a good castile soap, with or without the yolk of an egg, is a suitable application for a shampoo. A thorough brushing in a scalp somewhat anemic may promote the growth of the hair by stimulation of the scalp, but otherwise has no effect upon the hair.

The corium, or cutis proper, derma, or true skin, consists of connective tissue, muscle, nerves, blood-vessels, and lymphatics. The fat connective tissue lies in the deepest layer and gives to the body its appearance of roundness or plumpness when plentiful, and its disappearance in wasting diseases or senile changes produces the wrinkled or flaccid character of the skin. The nutrition of the epidermis is through the vascular supply of the corium, which is under the influence of the nervous system—hence the value of a normal condition of the nervous system regulating the blood supply that should be rich and pure.

Due consideration should be given to various habits of life; to proper foods, clothing, cleanliness, light, and exercise. The condition of the skin is influenced by diet, an improper one causing digestive disturbances which result in a toxemia that may produce a flushing of the face especially, or of other parts of the body, or lead to some form of skin eruption. It will scarcely be necessary to enumerate the various kinds of foods which are indigestible, especially when they are taken at improper or irregular hours, which is the cause directly or indirectly of many diseases of the skin. Alcohol frequently plays an important part as an indirect cause of acne, rosacea, and eczema, for instance; beer may, and often does, cause spots and redness of the face and nose, but a large majority of the cases, occurring as they do in young women, or in middle aged women, many of whom do not touch beer at all, much less brandy or other spirits, have been caused, not by alcohol but by improper foods, especially sugar. The diet should therefore be simple and wholesome, one which produces no indigestion and consequent toxemic conditions; and where there are individual peculiarities certain articles of food, such as shellfish, strawberries, etc., must be avoided.

The skin in a healthy state cannot be considered an absorptive tissue, as, for instance, it does not, beyond the outer layer, absorb water or watery solutions of any kind. This is also true of alcohol and alcoholic solutions. Any substance which de-
stroys the epidermis or exposes the rete layer can be absorbed, and any substance which when rubbed firmly into the skin and into its pores, causing a separation of tissue elements, can be absorbed. All substances that dissolve in hydrous wool fat, or mix with it, can pass through the epidermis, as nicotine, camphor, etc.; while those substances which are insoluble in lanolin and which also do not dissolve in neutral fats are not absorbed—such as potassium iodide, sodium chloride, arsenic, etc. Fats or oily substances may be passed into the pores if much friction with considerable pressure is used in the process of application to the skin, as some portions may be taken up and carried by the lymph or bloodvessels into the general system. There is in reality no such thing as a skin food in the ordinary use of this term.

Among other important influences operating on the skin in an injurious manner, unless properly regulated, are the extremes of temperature to which we are subjected by the character of the climate we live in, with its very great changes. The influences of climatic conditions and weather changes on the skin, as an organ of secretion and excretion, are marked and of great importance. Increased temperature of the surroundings causes the skin to become red, while there is profuse secretion of sweat. Heat produces directly some diseases of the skin; cold also may act in a similar manner. Care should be exercised in the selection and wearing of clothes. The following requirements are given by Treves:

First, a perfect covering for the body; second, maintenance of an equable temperature; third, absence of superfluous material or needless weight; fourth, noninterference with any of the functions of the body.

Cleanliness is absolutely essential to the correct performance of the functions of the skin, as dust and cast off epithelial scales must be removed by frequent washings. For the preservation of the skin, particularly where a tendency exists to irritation and tenderness of this structure, one must regulate the use of soap and the bath. By the use of soap the fat on the surface of the skin is emulsified, and with a normal skin no decided stress need be placed upon the kind of soap used, except that it should be of good quality. All soaps are combinations of fatty acids with alkalies. Potash is the alkali used to form soft soap, while soda in combination with fat produces a hard soap. A soap is neutral when the alkali merely balances or is in very slight excess of the fat. Medicated soaps have no special therapeutic value. Where there is sensitiveness of the skin, irritation, or inflammation, it is advisable to use a neutral soap, as the action of a strong soap is like that of caustic. As an example of a non-irritating soap, genuine castile soap may be mentioned. Such a soap, if any, should always be used on a tender and dry skin, as it does not remove too much of the normal fats of the skin; the latter being necessary for a soft and supple epidermis. The object of a bath is to promote cleanliness of the skin and to exercise a tonic influence on the general system. In the so-called blackhead, or comedo, condition there is always a thickening of the outer layer of the skin that prevents the passing out of the fatty matter and the excessive number of cells collected. This condition may be improved by the use of soap and water. One who has a thickened skin, with a comedo condition, should wash the parts daily with soap and water, using friction. The products of decomposition, such as the fats turning into fatty acids, can thus be removed. The softening effect of water on the skin is marked. It is shown in the Turkish bath on persons who do not bathe frequently, when the upper layer of the skin comes off in rolls. This effect of water should be utilized for the prevention of localized thickenings. The daily use of a foot bath for ten minutes, with or without the addition of soap, followed by rubbing to remove the superficial layer, often protects from the formation of corns. The cold bath is valuable in maintaining the normal nutritive condition of the skin. It acts as a tonic measure through the nervous and vascular system. The addition of various mineral substances (such as table or sea salt) are of no benefit regarding the nutrition of the skin, and may do harm by causing irritation. Oily, fatty substances, such as olive oil, hydrous wool fat, petrolatum, cold cream, or glycerin and water, should be used to supply the loss of the natural oil in cases of frequent washings where the excessive amount of fat has been removed by soap and water. Persons having thin skins do not require as frequent washings as those with thick and oily skins. Massage is used with the idea of toning the skin, removing or preventing wrinkles, and for removing fat in cases of double chin, but it is more of a luxury than a benefit, and can be replaced by the ordinary means of cleansing the skin with soap and water and by friction. Steaming of the face, with subsequent washing with soap and water, is of no benefit excepting in so far as it thins the upper corneal layer, possibly making a clearer complexion. Previous infestation of the skin with hydrous wool fat, or with pure white petrolatum, is the simplest way to avoid solar erythema and pigmentation.

Conclusions.

The use of ointments, so called skin foods, and chemical depilatories for cosmetic purposes should be avoided.

The natural complexion resulting from correct diet, regular hours, rest, the use of a neutral soap, and the avoidance of all foods and drinks that cause indigestion and lead to toxemias and disturbance of the nutrition of the skin, is preferable to all artificial ones, and prevents the premature old age condition of the skin.

When the condition of the skin depends upon the abnormal action of some other organ or organs of the body, a competent physician should be consulted.

The alluring advertisements of beauty specialists should be disregarded.

For the normal nutrition of any tissue or organ of the body there must be a normal amount of healthy blood passing through the part, nourishing it in a given unit of time, and the tissue itself must not be acted upon by injurious agents from any direction, within or without. The statements contained in this paper are based upon this fundamental fact, and a due appreciation of its correctness must be the guidance in matters concerning hygiene of the skin.

150 West Forty-ninth Street.
INTERNAL CAUSES OF SKIN DISEASES.*

By A. Schuyler Clark, M. D.,
New York.

If I can, in the space of time allotted to me, impress upon your minds the very important fact that the skin is not only a covering for the body, to protect the other tissues, and for the adornment of both sexes, but that it is also an exceedingly important organ of secretion and excretion—being intimately connected with the life and health of the bearer—I will feel that these few words on the internal causes and the relations of skin diseases have not been without avail.

Physiologically, I have but to mention its importance in the preservation of the normal body temperature, by the myriads of sweat and oil glands and minute bloodvessels with which it is supplied, and not solely by virtue of its use as a simple covering, as we are so apt to think. Also, that as an organ of excretion it rids our bodies depending on the degree of activity required of it of from one half to even more than the amount of waste and poisonous products that are regularly excreted by the kidneys, which of course explains the deaths reported as the result of gilding and varnishing the skin of the entire or greater part of the body, and in a measure also the seriousness of extensive burns of the body surface, though to my mind the toxemia or poisoning resulting from absorption of the destroyed tissues plays an equally important rôle. And, again, that in various constitutional diseases certain regular skin manifestations are present and traceable directly and solely to this internal cause, i.e., the eruptions of the various exanthemata such as measles, scarlet fever, smallpox, etc. the cachexia of cancer, jaundice in diseases of the liver and its ducts, and the various eruptions following the internal administration of certain drugs and the ingestion of various articles of food, such as shellfish, strawberries, tomatoes, etc.

May I here also advocate my belief in a general way in the importance of the consideration of the internal secretions and excretions and the constitutional condition as a whole, as predisposing causes in skin diseases of a distinctly parasitic origin and those precipitated by other external causes, for, by such a consideration can we in the treatment of this class of skin conditions, often shorten their duration, and even quite quickly and permanently relieve some of those, which have for long periods of time proved rebellious to purely local means of treatment; indeed, the internal inherent resistance against the various microorganisms that are constantly present on our skins saves us from frequent or constant afflictions with pimples, boils, the contagious form of dandruff, barber's itch, the so-called parasitic eczemas, and various other skin diseases, to say nothing of the more serious and general infections with tuberculosis, syphilis, and the other blood poisons that so often have their portal of entry in the skin. Given an unhealthy skin, which usually implies an unhealthy body, and these germs creep in, like the thief in the night, through the smallest crack or cut; but, given a healthy body with a healthy skin, or make that body and skin healthy, and they cannot enter, or in the morning they wither and are cut down. This immunity, natural or acquired, applies to the skin infections in the same way in which it does to diseases of the other organs of our bodies, such as diphtheria, typhoid fever, and the various general infections.

The previous speaker has told you of the external causes of an unhealthy skin—will you let me in a general way recall to you some of the internal causes occurring in our daily lives, of which all of you have so often heard, but equally often most of you, I am afraid, have forgotten to avoid, before I go on to a more specific classification and particularization. Of prime importance I would mention an insufficient intake of water during each twenty-four hours. Women are particularly poor water drinkers, and too often pay the penalty with a chronic constipation, faulty skin elimination, and kidney irritation. Eight glasses of water a day for the average male and from six to seven for the average female is the smallest daily allowance that should normally be considered. The taking of fluids with the meal, whereby a proper mastication is avoided, gastric juices are diluted, and stomach digestion as a result is incomplete, is a frequent cause of skin and body troubles. Overindulgence in eating, with a resulting deficient oxidation in the liver of the excess of foodstuff and an increased elimination of toxic products through the skin, of course, as well as through the kidneys, predisposes to skin irritation and disease. The obesity often resulting, with its accompanying relaxation of the muscles and tissues is so frequently accompanied by acne, eczema, and rosacea that it cannot be disregarded as a predisposing condition. Rapid eating and insufficient mastication, favoring excessive eating and imperfect digestion, is a frequent cause of kidney, liver, and skin diseases, and eating between meals, which ordinarily implies the eating of cooked sweets (in themselves frequent causes of digestive disturbances) requires an excessive amount of work on the part of the digestive apparatus, without suitable periods of rest; resulting in loss of appetite, impaired nutrition, and indigestion, and has a consequent effect on the skin. The lack of fresh air, exercise, sufficient rest, and the other sins of omission, and overwork, worry, abuse, the habitual use of poisons, and the sins of commission that harass our nervous systems are contributing causes, because of the intimate relation between the body and the skin. And finally, tardy and incomplete evacuation of the bowels, the so called constipated habit, is the last contributing stroke, and the pasty yellow skin that signifies this condition you have all frequently recognized. In short, all these general conditions I have enumerated as contributing to disturbances of the skin are exactly the same general conditions that make for ill health in the body at large, and I have come to regard certain toxic skin manifestations of the greatest ultimate benefit to my patients, in that they

*Prepared at the request of and read before the Public Health Education Committee of the Medical Society of the County of New York open meeting, at the New York Academy of Medicine, March 13, 1913.
serve as red flags of danger of more serious internal conditions to follow; so that when they will take these warnings to heart they can frequently be restored to good health, and irreparable damage to their livers, kidneys, and other vital organs be avoided. Exactly what the predisposing cause in each particular case is, it is often difficult to determine, but a complete and painstaking examination of the patient subjectively and objectively, of his urine, blood, and spinal fluid, and by inoculations, one can frequently discover excellent suggestion for lines of treatment productive of a most happy result from the patient's point of view, as well as the doctor's.

The internal causes of skin diseases may be classified, if you like, in the following way:

I. TOXIC CAUSES.

A. Of intestinal origin:
1. Toxic foods and drinks, i.e., shellfish, strawberries, tomatoes, stale foods of any kind, wines, liquors, tea, coffee, and tobacco.
2. Protein toxemias from imperfect digestion of animal foods; individuals often evince an idiosyncrasy for some particular meat, while even milk is toxic for some persons.
3. Carbohydrate intoxication from faulty digestion of sugars, starches, and, particularly, cooked sweets.
4. Intoxication from imperfect fat digestion, such as is frequently seen in babies. There is an old and true adage that a baby who spits up rarely has eczema. Eczema babies do better on a low fat content in their feedings.

B. Of autotoxic origin. About these intoxications we know, I regret to say, comparatively little as yet, but they have to do with disturbances of the internal secretions, i.e., of the thyroid gland, pituitary body, adrenals, spleen, etc., and are disturbances of metabolism.

C. Originating from the toxemias of certain diseases, i.e., the contagious eruptive diseases, diabetes, Addison's disease, etc.

II. NEUROTIC CAUSES.

1. Mental overwork, worry (often seen in the circumscribed, patchy eczema on the hands and arms of school teachers).
2. Severe shock, neurasthenia.
3. Reflex, as, for example, the eczema of dentition, which certainly is in part, at least, of neurotic origin.

III. CIRCULATORY CAUSES.

From various diseases of the heart and blood vessels, resulting in more or less severe and constant changes in the circulation of the skin, as in varicose eczema of the legs.

IV. ELIMINATIVE AND SECRETIVE CAUSES.

1. Imperfect elimination on the part of the skin itself, with retention of toxic and other products in the skin for a greater or less length of time, and imperfect functioning of its subaceous and sweat glands.
2. Deficient kidney elimination, either functional or organic, resulting in extra work being forced on the skin as an organ of excretion.

3. Torpidity, congestion, or disease of the liver, as in the so called gouty and uric acid eczema, whatever that may mean.

V. SEXUAL CAUSES.

1. Disturbances of menstruation of whatever origin.
2. Pregnancy.
3. The menopause.
4. Sexual abuse.

VI. ANEMIA AND DEBILITY.

Illustrated by the acne of chlorotic girls and the eczema and pruritus of old age.

I will now take up briefly a few of the commoner skin diseases and mention the more important predisposing causes in each particular instance, as determined by competent observers.

Eczema. The most frequently observed of all diseases of the skin. Among the internal causes may be included:

Prolonged administration of certain drugs, i.e., arsenic, the bromides, iodides, etc. Also the use of alcohol, tobacco, tea, and coffee.

Excessive eating of meats, particularly fried and salt meats and those of the higher protein content, i.e., liver, sweetbreads, kidney, etc. Individuals often have a susceptibility to untoward effects from some particular meat, and don't let us forget that it is sometimes one of the so called white meats too. A safe rule is never to take meat of any kind more than once a day.

Sweats in excess, and especially cooked sweets, such as pastries, pies, cakes, candies, and sweet desserts. There is a recognized patchy eczema around the mouths of boys and girls with a more or less constant history of excessive candy eating.

Eczema in fat babies (and here is where it usually occurs) can often be permanently relieved only by lowering the fat content in the feedings, or even putting the baby on a fat free milk until a well marked improvement is established. Any article of diet producing gastric or intestinal indigestion, whether from a personal idiosyncrasy or from its method of preparation, as very rich or fried dishes, predisposes to eczema in people whose skins are inclined that way. Overwork and worry are frequent causes, as evidenced by the anal and scrotal eczemas of many of our men of affairs. A chronic congestion in any part of our skins, but particularly that of the extremities, makes us susceptible, as in heart disease, thickening of the arteries, and varicose veins. Constipation, the gouty and uric acid diathesis, diabetes, organic and functional kidney disturbances, torpidity of the liver, and the other metabolic disturbances less well known and depending on the activity of the internal glands are too frequently the cause of an attack or a recurrence of an old eczema. The menopause often marks the first appearance of an eczema, and some women have eczema throughout their pregnancies. The menstrual period is often the time when eczema patients will be most annoyed, and this is particularly true if there are menstrual difficulties present. There is quite a characteristic papular eczema in young children and chlorotic girls which cannot be cured until the general condition
is improved and the anemia relieved. Eczema and pruritus in the very old are exceedingly chronic, and can be relieved only by constitutional treatment, if at all.

Acne and acne rosacea are two diseases closely allied, in which the predisposing causes play by far the larger role. Certain drugs are prone to produce the former when administered internally. Prominent among these are potassium iodide and the bromides, the so-called spring tonics and blood purifiers, and the various bromo preparations sold over the drug counter being large contributors. Alcohol, tea, coffee, and tobacco are causative in both acne and rosacea. In a general way gastric indigestion predisposes to rosacea and intestinal indigestion to acne, and the constipated habit is a predisposing cause in both conditions. Circulatory disturbances resulting in a congestion of the skin also favor both conditions; in fact, a congested sluggish circulation with capillary dilatation is itself a part of rosacea, and how frequently do we hear complaints of a cold and clammy skin, particularly of the hands and feet, in persistent acne cases. We all know how prone acne is to appear at puberty, and to flare up at each menstrual period, or be aggravated by sexual abuses. Torpidity of the liver, overeating or improper eating, and imperfect kidney elimination of the suboxidized products of digestion are quite regularly present in acne rosacea. Anemia, debility, and malnutrition, with the resultant relaxation of the tissues, are conditions that often have to be combated before we can make any permanent impression in some acnes.

Urticaria, toxic erythema, erythema multiforme, purpura, and angioneurotic edema. These may be grouped together from a causative point of view, and frequently the internal causes are the only ones that can account for them. Among these are: Certain drugs, i.e., cubeb, copaiba, quinine, belladonna, the coal tars, veronal, and others of the hypnotic group, and, not infrequently to-day, antitoxins, vaccines, and serums.

Intestinal toxemia from stale articles of food, especially cold storage meats (particularly pork and veal), oysters, fish, crabs, lobsters, nuts, mushrooms, strawberries, and tomatoes.

Intestinal worms in children.

In their more chronic form from proteid and carbohydrate indigestion, these skin conditions frequently cannot be modified until the patients are put on a meat free or starch free diet. What is one man's meat is so often another man's poison, and idiosyncrasy enters so strongly into the causation of these conditions, that they are often hard to control and to prevent from returning. Again, constipation, the gouty and uric acid condition, and the torpidity of the liver that usually go hand in hand with them, together with an imperfect kidney elimination, constitute a symptom complex frequently to be combated. Pregnancy, menstrual disorders, and the menopause favor their chronicity. Many observers go so far as to say that there is always a neurotic element present, and they may be borne out by the sudden appearance of one of these troubles following shock, fright, anger, or grief. These, however, may act only indirectly by causing a sudden stopping of the digestive process, with fermentation and intoxication resulting. Personally, I believe, from the effect I have seen from adrenalin in urticaria, the disturbances in the adrenals, thyroid, and pituitary body have an important bearing; but in exactly what way, I cannot say.

Dermatitis herpetiformis, pemphigus, and other bullous eruptions. These were formerly believed to be of neurotic origin, but various authors of late have ascribed an internal toxemia, probably of intestinal origin, as causative in these diseases.

Lichen planus. This seems to occur in neurotic persons, and frequently follows worry, overwork, anxiety, nervous shock, and exhaustion.

Allopecia areata. This, as has recently been observed, frequently occurs in individuals with disturbances of vision.

Herpes zoster, or shingles. With its severe neuralgic type of pain, this skin lesion is regularly located in the skin over the nerve terminals.

Folliculitis, boils, and carbuncles. These have for a long time been considered indicative of a run down state, and the lack of resistance against these infections is certainly of internal origin.

And so might I go on, if time would permit, enumerating internal predisposing and exciting causes of specific skin diseases. Suffice it to say that they do almost invariably exist, and that the successful dermatologist must be a reasonably good internist. Preventive medicine is as applicable in diseases of the skin as it is in diseases of the other organs. If you would preserve your skin, conserve your health by moderation in all things.

38 East Forty-ninth Street.

THE EXTERNAL CAUSES OF SKIN DISEASES.*

By George M. MacKee, M. D.,
New York,
Instructor of Dermatology, College of Physicians and Surgeons, Columbia University; Chief of the Dermatological Department of Vanderbilt Clinic; Consulting Dermatologist, St. Vincent's Hospital.

And John Remer, M. D.,
New York,

This, the external causes of skin diseases, is a subject that is associated with considerable interest and importance. It would be possible, under favorable circumstances, to write a long paper, dealing with the question, that would be very instructive and entertaining. For instance, in the case of cutaneous inflammation due to poison ivy, it would be valuable indeed to enter into a description of the various poisonous members of the rhus family, where they are found, how to avoid them and, finally, the symptoms, complications, sequelæ, and treatment of the affections caused by them. That I have limited myself strictly to an enumeration of the external causes of skin diseases, as recognized by dermatologists, and that I have avoided references to prophylaxis, consequences, description of disease, and hygiene.

*Prepared at request of, and read before, the Public Health Education Committee of the Medical Society of the County of New York, open meeting at the New York Academy of Medicine, March 13, 1913.
and treatment is partly because of the fifteen or twenty minute time limit, and partly because the other essayists of the afternoon will elaborate on the questions that I have avoided.

The external causes of the various cutaneous disorders may be divided into two general divisions: First, parasitic; second, nonparasitic. The parasitic can now be subdivided into animal and vegetable.

Animal Parasites.

_Acarus scabiei._ In this country one of the commonest animal parasites is the _Acarus scabiei_ (itch mite). The female insect burrows under the epidermis looking for a suitable place to deposit her eggs, leaving a trail of excrement that excite itching, inflammation, and other symptoms, and producing a disease known as scabies or the itch.

_Pediculi._ Equally common are the various forms of pediculi or lice—_pediculus capitis_ (head louse), _pediculus corporis_ (body louse), and _pediculus pubis_ (pubic or crab louse). The body louse inhabits the underclothing, the head louse ranges freely over the scalp, being protected by the hair, and the pubic louse attaches itself to a hair close to the skin. The saliva of these insects produces intense itching, with consequent excoriations, infections, etc., the sum total of which is known as pediculous capitis, corporis or pubis.

Miscellaneous animal parasites. The brown tail moth (1), a recent arrival in this country from Holland, produces an inflammation of the skin known as brown tail moth dermatitis. It is probable that the "nettling" hairs of the moth and its cocoon and caterpillar are responsible for the cutaneous irritation which is usually on the exposed parts of the body. _Pediculoides ventricosus_ (2). The dermatitis produced by this insect is known by the names, straw or grain itch, acarodermatitis urticarioides, mattress itch, etc. The eruption is widespread and consists of papules, macules, urticarial wheels, vesicles, and pustules. The flea, the bedbug, woodtick, guineaworm, _Acarus follicularum_, gaddly, and various other animal parasites of temperate and tropical climates (3), too numerous to mention, may produce inflammation of the skin. It might be added that as a rule the eruptions caused by animal parasites are not difficult of diagnosis, but associated secondary eruptions, such as eczema, may prove an embarrassing complication.

Vegetable Parasites.

The vegetable parasites are of rather more importance than those of the animal kingdom because of the numerous and complex types of eruption produced and, at times, the difficulty of diagnosis. _Achorion Schoenleinii_. This is the etiological factor in favus, a disease which may attack any part of the body at any time of life.

_Trichophyton_. There are several varieties of the ringworm fungus, but time will not allow of their enumeration. Suffice it to say that these fungi cause a rebellious inflammation of the scalp in human beings under the age of puberty. Thus, tinea tonsurans is a rare affection in the adult, but extremely common and troublesome in children. According to the variety of fungus, there may be only a scaliness and alopecia, or there may develop large vegetating tumors. Parasitic syicosis, or tinea barbe, is a similar affection of the beard region of male adults. In the skin the fungi produce scaly, circinate, easily cured lesions familiar to you all. Quite recently Whitfield and Sabouraud (4) have demonstrated that the so called eczema of the groin and that between the fingers and toes is of vegetable parasitic origin. And in this connection it must not be forgotten that the so called eczema marginatum is caused by the ringworm fungus. There are some special forms of ringworm which should be briefly mentioned. _Tinea imbricata_. This is a disease of tropical countries due to a fungus closely resembling the trichophyton but possibly belonging to the aspergillus. _Microsporon furfur_. This fungus produces a fawn colored, slightly scaly eruption known as tinea or pityriasis versicolor. It is at times confounded with chromophytosis and other forms of pigmentation. In passing, erythrasma, dolly itch, and pinta may be mentioned. Most of the vegetable parasites are transmitted from one patient to another, but it must not be forgotten that domestic animals harbor some of these organisms.

Leaving the ringworms, we come to parasites which by local inoculation produce cutaneous affections of a serious nature.

_Acetanumyces or Ray fungus_. This parasite is the causative factor in actinomycosis or lumpy jaw, a serious diseases that is often confounded with syphilis, tuberculosis, and other diseases. The symptoms consist of nodules and ulcerations. The disease is usually limited to the mouth and face and is seen mostly in those handling cattle.

_Blastomyces_. This is the organism of blastomycosis, a disease that is probably commoner than has been admitted and which, in all probability, is not infrequently diagnosed as syphilis or tuberculosis, drug eruptions, etc. The lesions are usually of a vegetating nature.

_Sporotrichum_ (5). This fungus produces an interesting disease (sporotrichiosis) that was little known until within the last two or three years. The lesions resemble syphilitic gummatas, and as they yield to antisyphilitic treatment, it is not at all unlikely that many cases have been diagnostic and treated as syphilis. The disease is seen mostly in those who come in contact with cattle.

Nonparasitic causes of skin diseases.

The nonparasitic causes of cutaneous inflammation, for the sake of convenience, may be divided into: First, bacteriological; second, chemical; third, traumatic; fourth, actinic; fifth, caloric; and sixth, miscellaneous.

Bacteriological.

We have many definite dermatological entities which are due to the growth of known species of bacteria in or under the skin. Strictly speaking, we should, in this paper, only mention the affections in which the bacteria gain entrance through abrasions in the skin and where these bacteria are the sole and specific cause of the disease.

_Bacillus tuberculosis_. When this organism is inoculated into the skin the result is usually a warty growth known as tuberculosis verrucosa
cutis, or anatomical tubercle. It may, however, produce lupus vulgaris or scrofuloderma, as is seen following ulcerative tuberculous adenitis. At times, also, ulcerations of the bucal mucous membrane may occur, often giving rise to considerable diagnostic difficulty.

*Spirocheta pallida.* The organism of syphilis interests us here only as the direct cause of the chancre and of syphilis.

*Bacillus acnes* (6). There is considerable controversy over the pathogenicity of this organism. It is possible that the early lesions of acne are due to the acne bacillus, while the pustules are produced by a complication with the staphylococcus.

*Staphylococcus.* The ever present staphylococcus is the cause of several cutaneous affections and is not above suspicion in others. The staphylococcus, together with a not very virulent strain of the streptococcus, are the active factors in that common disease impetigo contagiosa. The staphylococcus is usually responsible for the pustular lesions of acne, eczema, and many other affections. In fact, whenever cutaneous pus lesions exist the staphylococcus is likely to be at least a contributing element. This organism is the cause of sycois vulgaris, a persistent pustular folliculitis of the beard region, of furunculosis, and of carbunculosis, eczema, etc.

*Streptococcus.* As has already been mentioned, the streptococcus is an important factor in impetigo contagiosa, and it is possibly frequently associated with the staphylococcus in other pustular affections, such as erythema. A special form of this organism, the streptococcus of Fehleisen, is the probable cause of erysipelas.

*Misellaneous organisms.* Sabouraud, Unna, and others have isolated organisms which they assert are the producers of the various types of seborrhea. The *Bacillus mallevi* is the cause of glands, the *Bacillus anthracis* is the specific factor in anthrax, and an unnamed organism has been found in the erysipeloid of Rosenbach, an affection resembling a mild erysipelas occurring on the hands of those who handle fish; while the Ducrey bacillus is the cause of chanroid, etc.

It would not be profitable here to discuss or even mention all the conditions thought to be due to microorganisms. Psoriasis, eczema, and other common diseases are considered by many to represent the reaction of the skin to bacteria. Even malignant neoplasms have been placed in this category. Many of the constitutional diseases, such as leprosy and possibly many of the exanathemas, have their starting point in a local inoculation. In many of the bacteriological skin diseases there are important factors other than the bacteria themselves, such, for instance, as idiiosyncrasy, a lowered opsonic index, anaphylaxis, etc. While on the subject I would call attention to a condition known as infectious eczematoid dermatitis, described by Engman and Fordyce (7). It consists of a dermatitis of the skin of eczematoid type, following an initial ulcer, pyoderma, boil, etc. It is autoinoculable and probably due to the staphylococcus. Infantile eczema is possibly of this type, as well as the so called impetiginous eczema. Pustular and follicular eczema may possibly be placed in the same category.

**CHEMICALS.**

The skin reacts, often in a specific manner, to many chemical irritants. The term dermatitis venenata is given to an inflammation of the skin produced by the action of chemical irritants externally applied. Iodoform, chrysarobin, pyrogallol, and many other substances will produce a more or less violent inflammatory reaction in susceptible individuals. In the trades we find that varnish, dyes, paint, strong soap, certain woods, and many chemical combinations will effect an inflammatory reaction which, if allowed to continue, will develop into a dermatitis. The production of what is known as occupation or trade eczema. Knowles (8) and Fordyce (9) have written exhaustive articles on trade eczema, in which are enumerated all the various irritants which may produce this condition. Many plants contain toxic principles that can give rise to a very annoying eruption and, in some instances, as in the case of poison ivy (rhus), the outbreak is quite specific in its character. The eruptions produced by chemicals may consist of destruction of tissue by a caustic. A local hyperemia or inflammation, local or extensive vesication, edema, and even pustulation. In many instances the trouble will spread by auto-inoculation. Certain caustics like, for instance, nitric acid, may give rise to disfiguring keloids. While speaking of caustics it might be well to mention the intensely interesting disease known under the names of dermatitis facticia, malingering, or self-inflicted eruptions. In speaking of the action of chemical irritants intertrigo must be considered. This is a dermatitis of the parts of the body where two surfaces are in contact and where moisture, friction, and unhygienic conditions are likely to occur. Miliaria, or prickly heat, is another condition due partly to the action of perspiration that has not been allowed to evaporate, and partly to the friction of clothing.

**TRAUMATIC.**

Traumatism may produce slight wounds associated with reparative inflammation, or the injury may be associated with considerable loss of tissue. Gangrene may be a complication through interference with the circulation, while chronic conditions of a trophic nature might follow the effect on the nerve. Resulting scars may be disfiguring from a cosmetic standpoint, may interfere with physical functions, and, as sequelae, might be mentioned keloids and even malignant degeneration. Bacterial invasion is, of course, a constant menace.

**ACTINIC.**

Sunburn is the result, mainly, of the actinic action of the rays of the sun upon the unpigmented skin. Actinic light may be produced by electricity, and such rays will produce an erythema of the skin without the aid of heat. Some writers include sunburn or dermatitis actinica under the heading of dermatitis calcaria or erythema calorificum, as the case might be.

**CALORIC.**

Dermatitis calcaria ranges between a mild erythema to a severe and extensive necrosis. It may
be due to the sudden application of fire or other form of excessive heat, such as the actual cautery or an electric spark, or it may result from the long continued effect of mild heat. In this connection Hartzell (10) reports cases of a peculiar reticulated erythema associated with pigmentation, due to the heat from a stove, acting over a long period of time, and, also, the heat from a hot water bag. This condition is known as erythema ab igne or erythema ab calore.

**MISCELLANEOUS.**

Cold. In contradistinction to erythema, or dermatitis produced by heat, there is a more or less similar condition effected by lack of heat—excessive cold. A spray of ether, by robbing the skin of its heat, will produce a reactive erythema. The solid carbon dioxide, or liquid air, will produce an erythema or actual death of the tissue by freezing. Chilblain, or frost bite, occurs in all degrees of severity, and, even in mild cases, may cause more or less trouble for years. This condition is seen mostly in places of feeble circulation and is known as pernio, or dermatitis congelations. A combination of cold, wind, and light will produce erythema, scaliness, eczematous conditions, and telangiectasia. Corlett (11) believes that cold winds are capable of bringing about an entity which he designates as dermatitis hiemalis. That these factors may be a contributing cause in the production of other disease is seen in xeroderma pigmentosum and pelagra.

Röntgen ray. The x-ray, if the dose is slightly excessive, will produce an erythema, while, if greatly in excess, necrosis ensues, resulting in an ulcer that may fail to heal. Frequent, small doses over a long period of time will produce atrophy, keratoses, pigmentation, telangiectasia, and epithelioma, a condition similar to xeroderma pigmentosum.

This concludes a brief résumé of the external causes of skin diseases. Although a subject of considerable magnitude, it has been impossible to do more than to touch upon the most important phases in the time allotted for its discussion. I have limited myself strictly to the external causes, leaving a description of the diseases, their consequences, treatment, and prophylaxis to other speakers.

**THE THERAPEUTIC VALUE OF ORAL PROPHYLAXIS AND TREATMENT.**

By Gustav F. Boeime, Jr., B. S., M. D.

New York,

Assistant Visiting Physician, Department of Medicine, Outpatient Department, Bellevue Hospital; Clinical Assistant, Department of Neurology, Bellevue Hospital, West Side German Dispensary and Hospital, etc.

The treatment of the mouth and of dental conditions as a means of therapy is out of the routine of the average physician. Yet the neglect of the oral cavity by the practitioner, both as a means of diagnosis as well as of therapy, is all too prevalent.

The dentist has for years been calling attention to our carelessness in oral matters, and it is with regret that we must admit that the truth of the matter is that the physician is entirely too negligent in regard to these conditions. The therapeutic value of the proper care of the oral cavity is not a slight one, and such advice as we can give our patients will often cure, and in many instances prevent, much harm and damage to their health.

The subject will be briefly dealt with under the following headings:

1. The infant's mouth and teeth.
2. The adult's mouth and teeth.
3. Care of the mouth in pregnancy.
4. The care of the mouth in disease processes which are systemic or generally infectious, and which are aided by the proper care of the oral cavity.
5. Anteoperative and postoperative care of the mouth.

**THE INFANT'S MOUTH AND TEETH.**

(a) The care of the mouth and buccal mucous membrane before teething.

Oral infections and oral disease tend to create gastroenteric diseases in children. To avoid them rigid oral antisepsis and asepsis should be practiced. The bottle in which the milk is given (supposing that the milk is pure and fit for infantile consumption) should be properly cleaned—preferably in a solution of sodium bicarbonate at the boiling point. All particles of old milk should be removed. An unclean, previously used bottle should never be refilled, but a fresh clean bottle employed. The nipples should be boiled (even though boiling does tend to destroy five cent nipples rapidly) and then kept in sterile water. A fresh, clean nipple should be employed with each new bottle. The milk bottle once in the child's hand, the nurse should be taught to prevent the child from rubbing the nipple into its dirty clothes or carriage, or rolling it on the germ laden floor, which, while a roughly drawn picture, is...
all too prevalent. Personally, I advise patients to
have a specially constructed wire apparatus which
permits of free access to the bottle by the child at
feeding time, yet does not allow the child to throw
the bottle about.

This applies to the care of the bottle fed child.
The breast fed child is also entitled to cleanliness.
The mother should be taught proper personal hy-
giene. The nipples should be washed regularly with
boric acid solution, both to prevent fissures and in-
fection (in the mother, which is the usually as-
signed reason) and to prevent the feeding to the
child of infectious desquamated epidermis from the
breast. The mother should wear a clean gauze or
linen cover over her breasts and, before feeding,
should gently cleanse the nipple. It is certain that
this method will save much infantile oral infection
if properly carried out. The child should not be
permitted to suck its fingers or a nipple, or a so
called "comforter" (for the mother who is too care-
less or too inhuman to look after her child proper-
ly). These tend first of all to cause abrasions of the
oral mucous membranes, and, secondly, deform the
mouth of the child. Constant suction and constant
wear of hard rubber rings tend to deform develop-
ing alveolar ridges. If a child has regular feed-
ing hours and its food is properly prepared, such
barbarous instruments will be unnecessary. The in-
fant's mouth should be cleansed daily with a soft
piece of gauze and a mild alkaline or boric acid
solution. No great friction should be employed.
care however being taken that the recesses are
cleaned of food particles, and that the corners of
the mouth are clean.

(b) Dentition and its care.

As a rule, dentition is a process which needs no
further interference than as outlined above. Gen-

erally the first deciduous teeth appear between the
sixth and the ninth months, and the last in the sec-
ond year of life. They may appear earlier in syph-
lis or later in conditions of malnutrition. It occa-
sionally happens that a lower central incisor is pres-
cent at birth. If this interferes with nursing it should
be removed. It might here be pointed out that
"difficult dentition," or "the child is teething," is
too common an excuse for more important condi-
tions causing symptoms in a child, and that such a
diagnosis should be rejected until all other causes
are excluded or properly treated, if found. Holt
declares that "probably in ninety-five per cent. of
the cases in which symptoms are present they are
due to some other cause than dentition."

(c) Care of the deciduous teeth.
The child should be taught to look after these
teeth as carefully as of the later permanent ones.
The dentist should be regularly consulted, and then
chronic sore throats, enlarged cervical glands,
mumps, and many other infantile diseases will have
lost many of their terrors. Decayed teeth, improp-
erly cared for mouths, and enlarged tonsils are a
constant menace to the life of the infant. For chil-
dren a small toothbrush of medium hardness should
be employed. The dentifrice should be a liquid one
preferably, and the simpler the better; my prefer-
ence is for Seiler's, or boric acid, solution. It might
here be well to point out the importance of the phy-
sician to the dentist in this matter. When a dental

surgeon finds Hutchinson's teeth, late eruption, or
similar conditions (due to malnutrition, rickets, etc.)
it is just as much his duty to the patient to advise
proper medical treatment as it is for the doctor to
refer dental conditions to him. This conserves the
welfare of our patient, and, while seemingly a finan-
cial loss, will in the long run bring ease of mind and
results which are, after all, the aims of our profes-
sions.

(d) Anomalies and growths in the mouth as re-
lated to dental conditions.

Harelip and cleft palate should be treated as early
as possible, and by a capable surgeon. The most
perfect results, however, are obtained if the dentist
is consulted as to the proper alignment of the den-
tal ridges, the presence of impacted teeth, and other
conditions which tend to prevent a proper result.
The prominent premaxillar bone so frequently
present should be treated in youth by orthodontic
methods, while the jaw is still plastic.

Enlarged or pathological tonsils are attributed by
some to improper dental conditions. Others reverse
the opinion, and attribute poor oral and dental con-
ditions to the pathological tonsils. In any case
where the tonsils interfere with respiration, or cause
oral deformity or sepsis, they should be removed,
and such pathological dental conditions as may be
present properly treated.

THE ADULT'S MOUTH AND TEETH.

The teeth and the oral cavity should be kept

washrag, prepared to clean his teeth! The toothbrush should be of moderate stiffness and should preferably have a transparent celluloid back. The bristles should be firmly attached. Loose bristles are a constant menace. The brush should be washed thoroughly after use, and in the interval between use kept either in alcohol or in a weak dilution of formaldehyde solution (1 in 20) in a long closed container. This destroys bacteria and gives the patient a clean brush for use. I advise my patients to keep their toothbrushes in test tubes containing either of these solutions.

In brushing the teeth two things should be remembered: 1. That all the teeth are cleansed, and, 2. that the gums are not traumatized. Too many patients rub the brush too hard. It is only after the teeth, and consider that sufficient. The method advocated is, first cleansing of the molars, the inner, outer, and biting surfaces, then the front teeth, with a gentle circular motion, taking care not to injure the gums. The back of the teeth should also be cleaned at this time. Dental floss and toothpicks are to be condemned if placed in the hands of the laity. As a general result of their use the interdental triangular portions of the gums are driven back from the teeth, and in many instances set bleeding. Properly employed, dental floss may be of some value, but so rarely is this true that as a routine its use should not be advocated. Hydrogen dioxide, too, is to be laid on the shelf. First, it is not a germicide, and, secondly, it is only a poor antiseptic, and what is more important, it is harmful to the teeth, gums, and mouth. Usually it is acid in reaction, breaking down deposits of alkaline salts, or attacking normal tissue. If there are healing areas in the mouth it breaks down granulations. The bubbling and the frothing of the solution which makes so many users feel secure is only a mechanical cleansing, as the bubbling will occur with serum as well as with bacteria. The average patient should regularly consult his dentist, and in this way, beside saving his teeth, he protects himself from gastroenteric disturbances, nervous diseases of various types, malignant diseases, and a whole gamut of "the ills the flesh of man is heir to." E. H. Baker, in Dental Cosmos, mentions over one hundred diseases due to, or influenced by, dental conditions.

**Care of the Mouth in Pregnancy.**

An old adage is "For every child a tooth." What an insult to, and implication of, carelessness on the part of the medical profession this implies. Yet it is true that for years, and even to-day, physicians are afraid, for fear of interrupting pregnancy, to give dental anesthetics or to have the teeth of their patients treated. Doubtlessly dental extractions are to be avoided in the third, fifth, and eighth months of pregnancy because of the predilection to miscarriage or abortion in these months. Yet the mouth and mouth should certainly not be neglected. An abscessed tooth, a pyorrhea alveolaris, or chronically inflamed tonsil, means the swallowing of millions of pyogenic organisms in the food, means the absorption of pus and toxines (if not bacteria) into the blood stream from the gastroenteric tract and the gums. Add these to the existing influences of pregnancy, and why should there not be toxemias of pregnancy, apremias, and septicemias? This points to only one issue. Treat the oral cavity during pregnancy and we will have less cause to blame ourselves. When we remember that a pus appendix can be removed without interrupting pregnancy, why allow a "pus tooth" to remain? Again, it has been pointed out that many oral conditions during pregnancy seem due to topical reflexes from the genitalia. If this be true, the more reason for carefully watching the oral cavity. Three conditions especially come under our domain: 1. Sensitiveness of the teeth. 2. Loosening of the teeth and hypertrophy of the gingive. 3. Odontalgia.

The first two will be considered together. Beside the general care of the patient, the following treatment is advised. The patient should cleanse the teeth after each meal, preferably with an astringent wash. It is my habit to advocate one of the numerous zinc chloride solutions on the market. At first the patients complain of the peculiar astringent qualities, but most of them soon overcome this dislike. Daily massage of the gums with the tips of the fingers and cold water aids in hardening the gums, and soon the tenderness and loosening of the teeth vanishes. For odontalgia the dentist is to be consulted. This condition is often a neuroreflex, and no teeth should be extracted until the condition is treated neurologically. Here both professions overlap, and cooperative work leads to best results. Before leaving this subject it might be well to speak of the obstetric nurse. She, too, should have her oral cavity properly treated and her teeth in good condition. No nurse who is suffering from oral sepsis should be employed, lest she infect the patient or the newborn child.

**The Care of the Mouth in Disease Processes Which Are Systematic, or Generally Infectious, and Which Are Aided by the Proper Care of the Teeth.**

There is no field so interesting or as important as this one. Every nurse and every physician has seen cases in which the teeth are covered with sordes, in which the breath is poison to the attendant as well as to the patient, and in many instances the condition has been calmly attributed to the disease present, whereas proper oral toilet would have ameliorated these complications.

(a) Diseases of childhood. These have all been attributed to dental and oral conditions, and it is certainly true that they have furnished the aura for infection by improper oral care. And what is also of great import is the fact that the oral secretions and discharges are highly infectious in many of them. In all these diseases the teeth should be carefully inspected and such teeth as have cavities kept filled with cotton moistened with oil of cloves. If necessary, the dentist should be called in to put in a temporary filling. The nurse should be instructed to cleanse the mouth after each meal with a mild antiseptic lotion. The mouth should be rinsed out and the throat gargled (if the child be old enough). In younger children the mouth should be wiped out with a piece of moistened gauze, sprayed, or irrigated. Gum chewing is to be advo-
cated (as pointed out by Le Grand Kerr) as a valuable means of preventing sordes, and mechanically cleansing the teeth. A fresh piece of gum should be used every time. This does not, however, call for any carelessness in cleansing the teeth. It is merely a mechanical aid in the prevention of the deposition of material about the teeth.

(b) Diseases of adults. In typhoid fever or pneumonia no more incriminating monument to the neglect of the nurse and the physician can be pointed to than the mouth of a patient, the lips fissured and cracked, the teeth covered by sordes, and the tongue dry and bleeding, while the mouth teems with products of decomposition. As a rule this condition is included among the symptoms of typhoid or pneumonia, but it should rather be regarded as a symptom of carelessness on the part of the medical attendant or his nurse. In all febrile conditions the patient’s teeth and mouth should be thoroughly cleansed at least twice daily with a toothbrush and a mouthwash. After meals the mouth and throat should be thoroughly gaggled. The tongue should be cleansed with a tongue scraper or a piece of gauze. Gum may be chewed to prevent sordes. The lips should be kept moist with glycerin and lime water or with glycerin flavored with lemon. Such care will prevent many oral conditions present in these diseases, and when it is remembered that in seventy per cent. of the cases of typhoid the organism can be isolated from the teeth, that in nearly all cases of pneumonia the pneumococcus is found in the oral secretions, and that many other of the acute infections find their dangerous atra of infection in the mouth, careful oral toilet will prevent many of the complications so often calmly attributed to the disease process present.

(c) The use of the feeding tube. This as a means of alimentation may be allowed, but it may be pointed out here that the end of the tube had better be covered with a piece of rubber tubing as a mouthpiece, both to add to the patient’s comfort and to prevent pressure by the glass on the lips, gums, teeth, and palate of the patient. To prevent the staining of the teeth by iron preparations, or to prevent the deleterious effects of acids in mixtures, the use of the glass tube is farcical. The act of sucking through a glass tube is accomplished in something of the following manner: The tube opening is placed between the lips forward in the mouth, the back of the tongue is elevated against the palate, and the buccinator muscles contract inward; an inspiration is taken, negative pressure in the fore part of the mouth is produced, and the fluid is drawn into the mouth in and around the teeth; this is followed by the act of swallowing. Now the advice usually given to patients in regard to the use of the tube is that it is to be carried back in the mouth and suction is then to be begun. This is absolutely impossible, as any one can well demonstrate by an attempt to perform this manoeuvre. As the act of suction, then, distributes the acid and the iron well among the teeth, its purpose is lost. Far better would it be to give such drugs in pill form, if possible, or, if an acid must be given, give it much diluted and follow it with an alkaline mouthwash.

ANTEOPERATIVE AND POSTOPERATIVE CARE OF THE MOUTH.

This is of importance, especially when operations are to be undertaken on the gastroenteric tract. Moynihan and Cushing both try to make the diet preceding operation as sterile as possible, in order to lessen the number of pathogenic organisms in the tract at the time of operation. An essential factor to be remembered is that the oral cavity must be as nearly aseptic as possible during the use of this preliminary diet; otherwise these measures would be futile. The care of the mouth should be similar to that pointed out in the previous section on disease processes. A point, though, that we believe should be remembered is that the oral cavity should not be cleansed with any antiseptic solution immediately preceding an operation. At least three hours before the anesthetic is administered no oral antiseptic should be employed. This is for the theoretical and practical reason that normally the saliva contains an oxidizing enzyme which has both the qualities of an oxidase and a peroxidase. It is believed that because of this enzyme pneumococci and other bacteria are inhibited from acting as infective agents in health. The saliva also normally contains leucocytes with phagocytic powers. The saliva therefore acts as a preventive of pneumonia to some extent, and, if with the cold effect of the ether, we have the mouth cavity antiseptic, but not phagocytic, or enzymatic for the vicious organisms, we lay ourselves open to other pneumonias because of the solutions with which we destroy the saliva. The postoperative care of the mouth is similar to that of the mouth in health, unless special indications point otherwise.

NERVOUS DISEASES AND THEIR RELATION TO ORAL CONDITIONS.

This field is a vast one, and can be touched on but lightly here. The psychiatrist, the student of mental deficiency, the educator, have called our attention to the dental anomalies, anomalies of the dental arches, and of the palate in mental deficiencies and other conditions. And they have shown the beneficial result of the care of that all important region, the mouth. Judge Lindsey has called attention to a change even in moral character in young malefactors if these physical ills be attended to. The neurologist finds cause in impacted molars, in decayed roots, in peridental inflammations, for localized neuralgias, for headaches, and for ocular symptoms. If the case is properly diagnosed by the medical attendant and properly treated by the dentist, the patient will experience relief if not cure of many symptoms of nervous disease.

SUMMARY

This has been a sketchy picture of a large field. It presents no new material, no startling therapeutic measures; but it is an attempt to point out the seriousness of oral conditions in their relation to so called medical diseases. It is the details of treatment which lead to a successful issue in many cases, and certainly the treatment of the oral cavity is no petty detail.

220 Audubon Avenue.
THE BOTANIC FAMILY PHYSICIAN.

By William Renwick Riddell, LL.D., F. B. S. (Edin.), Etc.,

Toronto, Ontario,
Justice, Appellate Division of the High Court of Ontario.

In 1832 there was published at Hamilton, Upper Canada, a little volume which had considerable vogue in its day; but it is now rarely met with, and has passed into the limbo of forgetfulness.

At that time, with a few exceptions, no one could practise medicine—"physic" it was called—or surgery in Upper Canada without a license from the Governor, after an examination before a medical board appointed for that purpose. And this was not merely a prohibition on paper. Canadians have always had an awkward way of insisting upon obedience to their statutes; and in those days they were wont to hang horse thieves and burglars, and banish, flog, and pillory ordinary thieves and those guilty of less heinous crimes. So violators of the Medical Act did not escape. I have before me the proceedings in court in April, 1831, at York (now Toronto), when, before Chief Justice Robinson and a jury, Jackson Harrington was found guilty of a misdemeanor for "practising physic without a license."

There was nothing, however, to prevent anyone practising on himself and his own family, or advising neighbors about their health, so long as he did not practice for reward. Accordingly, the little book I have mentioned made its way into many a home and was the vade mecum of many a man who was charitably interested in the health of the community. The New Guide to Health or Botanic Family Physician, Containing a Complete System of Practice upon a Plan Entirely New, &c., &c., by Samuel Thomson, Hamilton, Printed by Smith & Hackstaff, MDCCCLXXII, is the title. My copy was once the property of the Rev. Henry Wilkinson, a well-known Methodist minister and once president of the conference.

Samuel Thomson is claimed as a son by both Massachusetts and New Hampshire. He was born in 1769, in territory now within the latter State; but at that time and till six years later the Provinces were under the same governor. The country was, as he tells us, "almost an howling wilderness," so that his "advantages for an education were very small." His mind, then, was "unshackled by the visionary theories and opinions of others," and "was entirely free to follow his inclinations by enquiring into the meaning of the great variety of objects around him." He found man to be composed of the four elements—earth, water, air, and fire. The earth and water were the solids, the air and fire were the fluids; the two first the component parts, the last two kept him in motion; and fire producing heat, Thomson came to the conclusion that heat is life and cold, death.

The theory upon which he based his practice of medicine is that the inside of the body should have ample heat, more heat than the outside. If the inside be allowed to become cold, "canker" is formed, which is the occasion and cause of disease. He nowhere defines "canker," but from many hints throughout the volume, he seems to have regarded it as a coating deleterious in its effects, which forms on the inside of the stomach and intestines when the inside is allowed to get colder than the outside, the "fountain lower than the stream."

"Heat is life and its extinction death, a diminution of the vital flame in every instance constitutes disease, and is an approximation to death. All then, that medicine can do in the expulsion of disorder is to kindle up the decaying spark and restore its energy." Accordingly, if a medicine is good in any case, it must be absolutely so in all; then its administration can produce the required effect in one case, it must in all, and "it is evidently immaterial what is the name or color of the disease, whether bilious, yellow, scarlet, or spotted, whether it is simple or complicated, or whether nature has one enemy or more." Extensive study and great erudition are not necessary to form the eminent physician. Knowledge of the origin of a malady and its antidote make the genuine physician; all without it is real quackery. In the "Preface written by a Friend," Thomson is made to repudiate the denomination "quack," but to accept that of "empiric," one who is governed in his practice by his own experimental knowledge. Thomson says he studied nature, made experiments for thirty years, and now can confidently recommend his system as salutary and efficacious.

He entirely disapproved of "bleeding and blistering and administering mercury, arsenic, nitre, antimony, opium, &c." But he also warns all against vegetable poisons which grow common in this country, garden hemlock, nightshade, apple-pear, poppy, henbane, poke root, garget root, wild parsnip, indigo weed, ivy, dogwood, tobacco, and laurel.

Six, and only six, medicines he has in his system of practice—"the first three are used to remove disease, and the others as restoratives."

"No. 1. To cleanse the stomach, overpower the cold and promote a free perspiration—emetic herb," i.e., Lobelia inflata of Linnaeus. This taken by the mouth is to "puke the patient," and may be prepared for use in three different ways: The powdered leaves and pods, a tincture made of the green herb, and the seeds powdered. Thomson does not say very much in the book about the use of lobelia as an enema. I have more than once heard my old preceptor, Dr. Richard Hare Clarke, of Cobourg, Ontario, one of the most successful of eclectics, describe the marvelous effects of an enema of hot lobelia seeds; but even he gave up its use as early as the sixties. Thomson says No. 1 "not only acts as an emetic and throws off the stomach everything that nature does not require for support of the system, but extends its effects to all parts of the body. It is searching, enlivening, quickening, and has great power in removing all obstructions." But it is not a complete cure in itself, "it soon exhausts itself, and if not followed by some other medicine to hold the vital heat till nature is able to support itself by digesting the food, it will not be sufficient to remove a disease that has become seated." What he means by "seated" or "settled" he explains in another place. By saying that fever is not a disease, but the effect of disease, the struggle of nature to throw
off disease, he goes on: "Support the fever and it will turn inside, the cold which is the cause of disease will be driven out, and health will be restored. In all cases called fever the cause is the same in a greater or less degree, and may be relieved by one general remedy. The cold causes canker, and before the canker is seated the strife will take place between cold and heat, and while the hot flushes and cold chills remain, it is evident that the canker is not settled, but as the contest ceases and the heat is steady on the outside, then canker assumes the power on the inside; this is called a settled fever."

After many experiments, he discovered "the best and only medicine" so to hold the vital heat; and this he calls "No. 2. To retain the internal vital heat of the system and cause a free perspiration." This is made of cayenne. He had tried ginger, mustard, horseradish, peppermint, butternut bark, and many other hot things, but settled down finally on cayenne, powdered and administered, half to a teaspoonful in hot water. He adds "a teaspoonful of Cayenne may be taken in a tumbler of Cider and is much better than ardent spirits." (Of course, de gustibus non est disputandum.) If cayenne cannot be obtained, red peppers, ginger, or even black pepper, may be employed as a substitute.

The next is "No. 3. To scour the Stomach and Bowels, and remove the Canker," i.e., "for removing the thrush from the throat, stomach, and bowels caused by cold; and there will be more or less of it in all cases or diseases, for when cold gets the power over the inward heat, the stomach and bowels become coated with canker which prevents the numerous little vessels calculated to nourish the system from performing their duty." He has adopted a rule by which to determine what is good for canker "to chew some of the article, and if it causes the saliva to flow freely and leaves the mouth clean and moist, it is good; but, on the other hand, if it dries up the juices and leaves the mouth rough and dry, it is bad and should be avoided." The root of the bayberry or cattleyberry, the root of the white pond lily, the inner bark of the hemlock, the root of the marsh rosemary, the leaves of the "witchhazel," of the red raspberry, both root and top of the squaw weed, are all recommended, but the preference given to the first; the last, it may be mentioned, "makes a very good bitter, tinctured with hot water and spirit, and is good for dizziness and cold hands and feet." This bitter, if the squaw weed is left out, is, it is understood, good for dizziness in another sense of the word "good."

This fact Thomson does not mention.

"No. 4. Bitters to correct the Bile and restore Digestion." Thomson warns us against supposing that the bile or gall is an enemy in case of sickness. There is no such thing as too much gall. "The difficulty is caused by the stomach being cold and foul, so that the food is not properly digested, and the bile, not being appropriated to its natural use, is diffused through the pores of the skin, which becomes of a yellow color... the only way to effect a cure is to promote perspiration, cleanse the stomach, and restore the digestive powers; which will cause the bile to be used for the purpose nature intended." He recommends bitter herb or balmony, poplar bark (either of the white or the stinking poplar), barberry bark, butter root or wandering milkweed, and the root of the golden seal—poplar bark rather preferred. We are told that "this is a very important part of the system of practice, for unless the food is digested it is impossible to keep up that heat upon which life depends."

Then comes "No. 5. Syrup for the Dysentery, to strengthen the Stomach and Bowels, and restore weak patients." The articles used in the preparation are, the bark of bayberry, peachmeats or meats of cherry stones, sugar, and brandy. Peachmeats are preferred, but still the meats of wild cherry-stones are almost as good—and a "tea made of the cherries pounded with the stones and steeped in hot water, sweetened with loaf sugar, to which add a little brandy, is good to restore the digestive powers and create an appetite."

The stock of medicine which will be "sufficient for a family one year, and with such articles as they can easily procure themselves when wanted, will enable them to cure any disease which a family of common size may be affected with during that time," is thus tabulated:

1 ounce of the emetic herb (lobelia). 2 ounces of cayenne. ½ pound of bayberry root bark in powder. 1 pound of poplar bark. 1 pound of ginger. 1 pint of the rheumatic drops (No. 6).

Thomson strongly approved of steaming; indeed, even his "system would in many cases without it be insufficient to effect a cure." His method was to take two or three stones and put them in the fire till red hot, then put them into a pan or kettle of hot water; the patient, undressed, with a blanket around him, is placed over the steam, preferably on an "open worked chair." The stones are renewed when cool.

The medicines are not to be given indiscriminately. "A regular course of medicine" is as follows: "First give Nos. 2 and 3, or composition, adding a teaspoonful of No. 6, then steam, and when in bed repeat it; adding No. 1, which will cleanse the stomach... when this has done operating, give an injection made with the same articles... in violent cases where immediate relief is needed Nos. 1, 2, 3, and 6 may be given together." No. 4 and No. 5 are for special cases.

Although these six medicines are all that are needed, Thomson gives the qualities of a large number of native plants—valerian, a nerve powder, spearmint to stop vomiting, peppermint and pennyroyal to promote perspiration, summersavory for toothache, hoarhound and elecampane for coughs, mayweed for a cold, tanzy and featherfew for hysterics, chamomile for bowel complaints, bitter-
sweet, mulein, and burdock for plasters, skunk cabbage for asthma, wakerobin for colic, slippery elm bark for sore throat, ginseng for nervous affection, chivers, snakeroot, mustard, &c., &c., &c. Many of these are still popular remedies.

Not all his science is to be found in this handbook; he had a system of midwifery and surgery. But all who wished to understand these “must purchase the right” which sometimes, at least, cost “twenty silver dollars,” and “all who purchase the right may receive the necessary verbal instruction to enable them to do all that is required in the practice of midwifery, as well as to be able to become their own physician and surgeon at a trifling expense.” That some in Upper Canada purchased the right is certain, that some of these passed the medical board is equally certain, that the results in many cases of the Thomsonian system were as good as those of the regular profession is also certain. Nor is this to be wondered at. There is extant the report of a case in which one physician in Upper Canada sued another for libel. At the trial, in 1827, it was proved that the plaintiff had bled a young girl several times within a few days, taking five quarts of blood from her; and had physicked a young man, who had a “touch of fever,” with calomel till “his mouth got raw and sore, his teeth loose, and his breath bad.”

The Botanic Thomsonian School or Physomedical School, though at first antagonistic to, gradually merged into, the Eclectic School. The opposition of these to the practice of bleeding had much to do with its comparatively early disappearance. They were not invariably successful in their practice; indeed, Thomson himself had the misfortune to run up against the criminal law in Massachusetts. In January, 1800, he was called to attend Ezra Lovett, Jr., at Beverly, Mass. He had come to that town the preceding month; and it is said had much vaunted the virtues of his medicines, which he called by such extraordinary names as “coffee,” “well-my-gristle” and “ramcats.” Lovett had a cold; Thomson ordered a large fire lit in his room, wrapped the patient up and gave him a powder in water, of course, lobelia, No. 1; this “pucked him.” Three minutes afterward he gave him another dose, which operated two minutes later; he repeated the dose with the same effect, all three doses within half an hour, the patient meanwhile drinking copiously of the “coffee,” which was proved to be an infusion of marsh rosemary mixed with bayberry bark, i.e., No. 3. The next day and next he was dosed with the same medicines, and on the following day he was sweated. The next two days the doctor did not appear, but on the following day he administered No. 1 and No. 3 again, and also the next day. The patient was now in great distress, and when the doctor asked him how far down the medicine had got, and he replied down to the breast, the doctor assured him that it would soon get down and unscrew his navel. The following day the patient became delirious and violent, but the doctor got one or two doses of lobelia down his throat, telling the patient’s father that his son had got the “hyps like the devil,” but that his medicines would fetch him down. The next morning the regular physicians were called in, but could do nothing for the unfortunate who died shortly afterward. Thomson was indicted for murder, and tried on December 20 at Boston, before Chief Justice Parsons and Justices Sewall and Parker, and a jury. It was proved that the death was due to the treatment which Lovett had received, and the prosecuting counsel stated that the prisoner had administered like medicines to others who had died in his hands. The only witness, however, who appeared, swore that he had taken the emetic medicines as the prisoner’s patient several times in two or three days, and was relieved permanently of his complaint, “an oppression at his stomach”; and there was no evidence that in the course of his very novel practice the prisoner had experienced any fatal accident among his patients. He was accordingly acquitted. The curious will find a fairly full account of the case in No. 6, Massachusetts Reports, p 134. The followers of Thomson boast that he was acquitted without being called on for his defence. The fact, however, is that he owed his safety to the charge of the chief justice, that if the medicine was administered with an honest intention to cure, however ignorant the prisoner might be of medical science, he should not be found guilty.

Thomson continued to practise in Massachusetts for many years, and died in 1843. I cannot find that he ever came in person to Canada.

There is no trace in this volume of some extraordinary views attributed to him by some medical writers, e.g., that as minerals lie in the earth, minerals given as medicine must tend to bring the patients down to the earth, while as plants grow up and away from the earth, medicines from the vegetable kingdom must raise up the patient and keep him from the grave.

TWO NEW TESTS FOR THE DETECTION OF DEFECTIVES.

By HOWARD A. KNOX, M.D.

Ellis Island, N. Y.,

Assistant Surgeon, United States Public Health Service.

It is a well recognized fact that the greater the number of tests (and the more varied their nature) used in diagnosticing a given defective, the more certain the examiner is that his deductions are correct. It is with this idea in view that these tests are given to the profession for what they may be worth in the special lines of work in which they may be used. In the detection of alien illiterate
morons they have been found to be of considerable value when used in conjunction with our other performance tests, and it is of interest in this connection to note that in May, 1913, one hundred and eight mentally defective aliens were detected by the medical officers of the United States Public Health Service at Ellis Island, and that the great majority of these were of the moron or higher defective class. This number is about four times the number of mental defects certified during the month of May, 1912, before our performance and other tests were developed and standardized for time, etc., to suit our special needs. In other words, we have broken new ground, as no one else seems to have worked with alien illiterate defectives and nowhere in the literature are these defectives described.

Figures 1, 2, 3, 4, and 5 represent the author’s "visual comparison" test, and Figure 6 B his modification of the Healy frame test. The legends will be considered sufficient description at this time, but to fully understand the use of these tests one should see them in operation with the stop watch. The line they draw between normal and defective illiterates is well marked, but, as in using other tests on the individuals, the general rules as to

![Figure 2: Envelope Section of the "V.C." test. As with the clusters in Fig. 1, there are here five pairs of envelopes, each pair being of different design. These envelopes should be "paired" in eighteen seconds after the attention is directed.](image)

![Figure 4: Moon Section of "V.C." test. The subject should be able to point out the four moons that are looking to the left in fourteen seconds, if he is directed to begin at the upper right hand corner and proceed systematically along each line, left to right.](image)

![Figure 3: Face Line Section of "V.C." test. To normal illiterates over twelve years of age (the entire test being standardized for illiterates over twelve years of age) four of these faces appear "sad" and four appear elated or "happy." Once the subject thoroughly understands, and his attention is directed, he should point out the "sad" ones in twenty seconds. If in any of these tests it appears that the subject does not understand what is wanted the test should be repeated twice for him, and time taken with the stop watch at each repetition. If after the three trials the subject cannot be made to understand what is wanted by the examiner or a competent interpreter, then the fact is evidence that he is defective.](image)

![Figure 5: The Key Section of the "V.C." test. The time "element has not been worked out for this section, but it is hardly the less valuable. "A" is shown, the subject and he is asked to find the nearest like it in Fig. 1. "B" is shown and he is asked to find it in Fig. 3. "C" is shown and he is asked to find it in Fig. 4. "D" is shown and he is asked to find it in Fig. 2, and "E" is shown and he is asked to find it in Fig. 4.](image)

![Figure 6: "A" shows the Healy frame test which has been a valuable test in our work, but somewhat too easy for our special needs; it having been accomplished frequently by accident. It consists of five blocks within a frame, the blocks to be put in as shown here, in fifty-five seconds (this time standard is for our cases). "B" shows the author's modification of the Healy test. The frame is diamond shaped and there are six blocks instead of five, and they are cut on the "bias" in order to fit into the diamond shaped frame. The "bias" does away with the element of luck, and, while easy to accomplish, it requires constant thought and attention.](image)
after all, are the principal ones to be considered from an eugenic standpoint.

In Figure 6, "A" and "B" the blocks should more closely approximate their frames and each other than the diagrams would indicate.

---

CEREBROSPINAL MENINGITIS.

Its Occurrence in New York City during Half a Century; References to Some Recent Literature.

By M. L. Ogan, M. D.,

Chief of Section on Typhoid Fever, Cerebrospinal Meningitis, and Poliomyelitis, Department of Health, New York City.

There has been but little cerebrospinal meningitis in New York city since 1905. During 1911, 314 cases were reported, with a fatality of 74.8 per cent, and a death rate of 0.47 per 10,000. Corresponding figures for 1912 were 268 cases, case fatality 72.4 per cent, and death rate, 0.36.

Notification takes place by telephone, postal card, or the name is taken from a dead list forwarded by the Bureau of Records for each borough. If the case is reported by a private practitioner, free consultation is offered to the physician through a clinician and bacteriologist of experience from the Research Laboratory, and, if accepted, lumbar puncture is performed, and antimeningococcus serum is introduced into the subdural space. Though the mortality continues high, owing to the delays in notification, a marked diminution in fatality has taken place among those receiving serum. Further consideration of such treatment will appear below. Hospitals having ample equipment for the management of these cases are not aided, except that the serum is supplied by the Research Laboratory on request.

The most unsatisfactory feature in our experience with this disease is the high proportion of cases reported to us for the first time on the dead list. Out of 105 consecutive fatal cases in Manhattan last year, forty-eight cases had not previously been reported. Every effort is made to eliminate the cases which seem after a careful survey of the history to be due to other causes than the meningococcus, though such exclusion is difficult and not infrequently impossible, owing to meagre case records kept by the patient. In nearly all the fatal cases except the fulminating type, pneumonia is present. When interviewed by a medical inspector, the practitioner will frequently amend his diagnosis to that of a terminal meningitis in the course of pneumonia. Conversely, of course, true cases of epidemic cerebrospinal meningitis may be reported as fatal pneumonia and escape consideration. After consultation with our inspectors some physicians have desired to change their diagnosis to tuberculous meningitis. The circumstances, when convincing, are reported to the Bureau of Records with the recommendation that the death be not charged to the epidemic form. Vital statistics of the department, it will be seen, are, despite all care, subject to error in respect to the case fatality. All cases of the epidemic infections type are isolated for at least two weeks, this being the period during which the specific organism is usually found in the nose and throat. On termination of the case by recovery, removal to hospital, or death, the sick room is fumigated and bedding disinfected.

Outbreaks are not very frequent, and show a remarkable periodicity, occurring about every ten years. In 1872, 1881, 1893, and 1904-5 the death rate per 10,000 of population reached 8.7, 4.2, 7.7, and 5.4. In the year after each outbreak the rate was above the average, but during the remaining intervening years it was very low. Thus, from the sixties up to 1872 it was less than one half of one per 10,000 annually, though steadily advancing. From then it rose to 1.5 in intervening years, then showed a tendency to decline, until the advent of lumbar puncture and bacteriological diagnosis, when the interim average fell at once below one per 10,000, due to the exclusion of many tuberculous and other cases from statistics. The effects of the great outbreak of 1872-3 are felt to the present time. These combined yields a death rate of 10.5. Never since that time has the rate come down to the one fourth of one per 10,000 which had characterized several preceding years, even with the aid of more exclusive diagnosis and serum treatment. Each of the two succeeding decennial outbreaks showed a marked tendency to a decline in severity, and the interval annual rate also was slowly falling until the remarkable outbreak of 1904-5. This, the fourth epidemic in a half century, was the severest of all, showing a death rate for the two years of 10.0, which is even higher than that of 1872.

Eight years have passed since that time, and the death rate has fallen from 1.02, in 1906, to 0.35 in 1912. Thus we have the great wave of 1872 following a calm and succeeded by increased average disturbance, but quieting down, rising to sharp but successively less formidable decennial crests until all the contributing forces formed the culminating wave of 1904.

These periodical outbreaks seem due to an accumulation of susceptibles, such as we see in other diseases, in infantile paralysis, for instance, about every two years, less strikingly, however, due to the greater infectivity. Frequently in infantile paralysis several members of a family will succeed, whereas in cerebrospinal meningitis seldom more than one member is affected. This allows, then, for a greater accumulation of numbers, and when conditions favor it the outbreak takes place. Each of the notable cerebrospinal meningitis years have been characterized by hard winters with much snow.

If the past is a criterion we may expect a sharp incidence rise in the next year or two if the meteorological conditions favor it. A moderate number of susceptibles are here, moderate because the severity of the 1904 invasion cleared the field. Following the law indicated above, the outbreak will not be so severe as those of 1872 and 1904. Cases are divided by intensity and evolution (Flexner) into:

1. Severe onsets, seldom terminating in recovery spontaneously.

2. Mild onsets which remain so or develop into severe cases, slowly progressive to recovery or death.
3. Middle course cases. Within these classes occur the
a. Fulminant with early fatality.

b. Ambulant in which recovery is the rule, but which may pass into violent intensity, even becoming fulminant.

c. Abortive, with recovery by crisis.

Ambulant and abortive cases are not to be confounded, the onset in the one being insidious, in the other, sharp.

The serum treatment with direct introduction into the subdural space has been distinctly beneficial, as shown by comparative studies within the period of bacteriological diagnosis. The years 1904-9 were characterized by epidemics in various parts of the world and subtended an average case fatality of seventy-three per cent. The lowest one considered being Milan, fifty-six per cent., the highest, in certain Ohio and California cities, ninety per cent.

It has been pointed out by Flexner that there is far less variation according to period, race, or occupation, than to virulence of meningococcus, and that there is a considerable biological variation, exudates showing a difference in number, containing sometimes a large, sometimes a small, number of cocci, the distribution of which varies in the ratio within the cell or free in the fluid. The prognosis in the latter event is more grave than in the former. In opsonic experiments, and by inference in man, "the kind of leukocytes and even sera, normal or immune, play no obvious distinguishing part." Most meningococci are readily phagocytized in the presence of serum and ultimately dissolved, some resisting more tenaciously, and it is from these strains digesting slowly that the antimeningoococcus serum is preferably developed. This indicates the great care essential in selecting a product from a reliable source. There is experimentally, however, at times "a fastness to intraleucocytic enzymes, preventing engulfing of the specific organism," which latter may in man account for some failures in serum treatment. Some other causes of failure are:
1. Dry cords with adhesions obliterating subdural spaces, which would include the basilar occlusion cases, and due to pathological sequence or even to serum irritation.
2. Sudden and pronounced fall in blood pressure, with respiratory paralysis.
3. Excessive temperature, possibly due to hastening of liberation of endotoxines.
4. Trophic disturbance in long treatments (skin, bladder, etc.).
5. Late treatment.

One observer suggests tricresol poisoning, due to fissure of cord allowing communication of the subdural space with the central canal and fourth ventricle. (Kramer.) This implies a chemical action on the meulci in the floor of the ventricle causing paralysis of respiration. Flexner nullifies this effectually by calling attention to the direct path to the fourth from the lateral ventricle, where phenolized serum has been introduced with no effect on respiration. The fatalities are clearly shown to have been due to an improper adjustment of the volumes of fluid removed and of the serum introduced, resulting in respiratory paralysis due to pressure.

Notwithstanding all difficulties, the case fatality in serum treated cases is reduced at least one half over the old rate of seventy to seventy-five per cent. Flexner's analysis of a world wide series of 1,294 cases shows a fatality of only 30.9 per cent.

When given first to third day of disease, 18.1 p.: cent. died. When given fourth to seventh day of disease, 27.2 per cent. died. When given later, 36.5 per cent. died. The least satisfactory age was under one year of age: 49.6 per cent. died. The most satisfactory age was under five to ten years: 15.1 per cent. died. From this the mortality increases to 37.5 for those over twenty years of age.

A tendency to termination by crisis was shown when the disease was treated early. Clark, at Swinburne Island, in eighty-five cases had a mortality of forty-seven per cent., including sixty-six cases with complications. Three patients had tuberculous nephritis and five secondary infections: ex luding which, the mortality was 37.6 per cent. DuBois, of the Health Department Research Laboratory, treated a series of cases with a mortality of fifty per cent., though many of these were seen late in their course. The most impressive figures are those of Sophian, who had a mortality of twenty-eight per cent. in Texas hospitals.

PRIZE ESSAYS.

Questions for discussion in this department are announced at frequent intervals. So far as they have been decided upon, the further questions are as follows:
CXXXVII.—How do you treat threatened abortion? (Closed August 15th.)
CXXXVIII.—How do you treat insomnia? (Answers due not later than September 15th.)
CXXXIX.—How do you treat chancroid? (Answers due not later than October 15th.)

Avoid answers one of these questions in the manner not satisfactory to the editor and his advisers will receive a prize of $25. No importance whatever will be attached to literary style, but the award will be based solely on the value of the substance of the answer. It is requested (that not required) that the answers be short, if practicable, no one answer to contain more than six hundred words; and our friends are urged to write on one side of the paper only.

All persons will be entitled to compete for the prize whether subscribers or not. This prize will not be awarded to any one person more than once within one year. Every answer must be accompanied by the writer's full name and address, both of which we must be at liberty to publish. All papers contributed become the property of the Journal. Our readers are asked to suggest topics for discussion.

The prize of $25 for the best essay submitted in answer to Question CXXXVI was awarded to Dr. Nelson Du Val Breed of Washington, D. C., whose article appeared on page 475.

PRIZE QUESTION CXXXVI.

THE TREATMENT OF CHOLERA INFANTUM.

(Continued from page 478.)

Dr. Hyman Goldstein, of New York, considers

Cholera infantum in its entity, is a severe gastro-intestinal intoxication. As to its etiology we should
consider it the result of one or more of the following factors, i.e., milk infection, germ disease, anaphylaxis of the organism produced by certain foods or fruits, impure water, chemical or biochemical irritants, weather influences, neurotic and emotional disturbances, dirty finger nails of mother, governor, or infant when feeding, dirty nipple or shield, germ carriers—as toys, flies, mosquitoes, winds, dust, sand, and insects. Basing the treatment on these facts leads me to divide it into two main divisions: Prophylaxis, and the treatment of the disease.

1. Prophylaxis.—(a) Hygienic precautions for the mother and governor, for the child, and for the home. The mother or governor should always have clean finger nails, clean habits, and a pleasing disposition, and be very patient but not emotional. The child’s body, finger nails, buccal cavities, gums and tongue should likewise be kept clean, the clothing should be clean, loose, plain, and without folds. The used nipple or shield should be washed and kept antiseptically clean. Breast feeding must be encouraged for young infants during the second as well as the first summer, even if it will require a wet nurse (who is healthy and young and has all the necessary requirements). To let the child play or roam about in the sand and dirt while the guardian is bathing should be prohibited.

Sweeping the floors or dusting about without watering is dangerous, because the flying dust contains germs which may spread infection. The table scraps and house refuse matter should be immediately gotten rid of, or placed in airtight covered receptacles; otherwise putrefaction will ensue. Worms will gather, and germs will thrive and spread disease.

(b) Dietary precautions.—Foods and fruits that irritate the alimentary tract should be prohibited, because there exists a susceptibility in the organism, and anaphylaxis sets in with marked toxicemic disturbances. In young infants, encourage breast feeding only, but in older children allow only easily digestible food, small in quantity and at frequent intervals, and watch closely for any mild gastrointestinal disturbances, which may necessitate a change.

(c) Climate.—Those who can afford it should take their children to the country for the summer months. The poorer class would benefit their children by taking them to the sea shore twice weekly, and during every hot evening. The very poor should take their children to the parks, river banks, piers, roof gardens, roofs, and in the shade to give them plenty of fresh air. All of these precautions when heeded by the mother, and a close watch on any change along the alimentary tract, I believe, in many instances would prevent the onset of cholera infantum.

It is also to be remembered that cholera infantum, like typhoid or other infections should be quarantined. The excreta should be received in special receptacles containing disinfecting solutions, likewise all soiled bedding and other things handled should be disinfected. Other children should not be permitted in the same room. It is advisable also that only one person should attend to the patient throughout the entire illness.

2. Treatment of the disease.—Besides quarantining the patient and disinfecting the excreta we must abate the marked prostration and fever, control the diarrhea and vomiting, modify the sepsis, stimulate the vital centres, and protect the outlets of life.

Food should be withheld for twenty-four to thirty-six hours. I allow a little buttermilk, which seems to lessen the infection, as it checks the diarrhea, and also sour grape wine (no sugar), which sustains the vital powers, and diminishes the prostration and vomiting. Small pieces of chopped ice should be swallowed, preferably, with a little orange juice.

At the outset administer fractional doses of colomel in combination with powdered ipecac, salol, and antimony, often repeated till one half grain is taken, and in children over six years, till two grains are taken. The ipecac in small doses soothes the mucous membrane, and the salol and antimony are antiseptic. This preparation gives excellent results. Three hours after the last powder, a moderate dose of castor oil is administered; if it nauseates I advise a high soap suds enema in its stead.

Two hours later, after the good results follow the cartharsis, begin with the astringents. Large doses of bismuth seem best. When the diarrhea is uncontrollable and depleting, paregoric, in minimal doses, well diluted, may be added, watching its effects very carefully; in very young infants the paregoric is not to be used.

For the fever, hydrotherapy is the best, such as cold water spouging, every two hours; place the child in a bathtub of warm water, in a sitting posture, and add water until it reaches the child’s umbilicus; spray cold water over the rest of the body. Cold sheets or a cold water coil is better where the temperature is very high and persistent. Another good remedy is to give a low enema of one glassful of cold water or administer it through a rectal tube, repeating when indicated by recurring hyperpyrexia.

To combat the sepsis administer salol, 1/2 to 1 grain, with thymol, 1/30 to 1/10 grains, every four hours, and continue it throughout the convalescence. Thymol has almost a specific action in these cases. The sour grape wine or warm whiskey, ten minims to a teaspoonful of warm water, every three hours, should be continued, and warm bottles to the sides and feet should be applied to keep the body warm.

After a few days when the diarrhea diminishes and the intense symptoms subside or lessen in severity, give albumen water, boiled milk and water, or a tablespoonful of milk in a thin gruel every hour. Then gradually increase the diet from fluid to soft in accordance with the improvement of the gastrointestinal condition, but solid food—white or red meats or scraped beef—are not allowed until about the latter part of the third or fourth week, and then only with drop doses of dilute hydrochloric acid, well diluted to facilitate digestion. As to the drugs, the salol and thymol should be continued for six weeks, and then give ten drops of the syrup of the iodide of iron every three hours as a tonic; or give the solution of iron, strychnine, and quinine, in ten drop doses, every three hours, when anorexia is present, with marked weakness. The sour wine should be continued, giving a teaspoonful every three hours, to stimulate and support the vital cen-
tres. The child should remain in bed for at least three or four weeks and then be allowed to sit up; after five weeks place the child on the porch, roof, or yard, to sit for a few hours, and then walk a little about. Electricity and massage also help to strengthen the body after such a protracted illness.

Dr. Frank W. Spicer, of Duluth, Minn, holds that:

The management and treatment of cholera infantum depends somewhat upon the severity of the symptoms. While primarily we are dealing with a severe form of gastrointestinal infection, it is essential to remember that it is the toxemia that causes the alarming symptoms; the toxemia being due to the absorption of toxic materials, the result of putrefactive changes in the stomach and intestines, caused usually by impure milk. The pathological changes in the stomach and intestines are slight compared to the severity of the symptoms. "The trouble is in the contents and not the structure." The toxemia causes great depression of the heart and the general system, by acting on the nerve centres, and the symptoms develop so rapidly (the course to a fatal termination is often only a few hours), that each case must be considered an emergency case that demands prompt and careful treatment and nursing.

The temperature should be taken frequently in the rectum, as the axillary temperature may be normal when a hyperpyrexia exists.

1. The first indication is to empty the stomach and intestines; cathartics cannot be depended upon, even if they are retained by the stomach, on account of the time necessary for them to act. Probably one washing of the stomach at the outset will suffice. The bowel should be irrigated with a normal salt solution—a pint for a child six months to a quart for a child of two years. This may be done several times the first day, then once daily. A flexible catheter should be introduced six to eight inches up, and a cold solution used if the temperature is high. The small intestine is not reached in this way, and as soon as the acute vomiting ceases, small doses of calomel and podophyllin should be given, followed by castor oil.

2. A cautious and judicious use of morphine in many cases has no substitute. It is valuable as a narcotic and hypnotic. Its effect upon the heart and nerve centres, upon the secretions, and in checking the continued loss of fluids, its effect on peristalsis in checking the forceful movement, and also in allaying the acute vomiting are all desirable. It should be given after the gastrointestinal tract has been emptied, and given hypodermatically in doses of 1/100 grain, with atropine, 1/600 grain, to a child of six months, which may be repeated. Starch water and laudanum, given by rectal injection, may be substituted in some cases. It is contraindicated when the little patient is drowsy or unconscious, and when the "hydrncephaloid" state, as it has been called, exists.

3. The next indication is to reduce the temperature. This is done by baths at 80° F., reduced to 70° F., by using sheets wrung out of cold water: an ice cap to the head; and by frequent rectal injections of cold water.

4. The next indication is to supply the shrinking body with fluid. Hypodermoclysis is the best method. Although the vitality is low, it is surprising how much fluid the tissues will take up. One pint to one quart may be given in twenty-four hours. This will aid in quenching the thirst, assist the action of the kidneys, and neutralize the poison.

5. Food and drugs. No food is given at all during the acute stage, as it is useless to try it. For the vomiting, a teaspoonful of equal parts of lime water and cinnamon water may be valuable. Stimulation may be necessary. Branlty and other stimulants may be given by mouth if retained, if not, camphor is reliable and can be given hypodermatically; also other heart stimulants. If a diarrhea persists a good prescription is

R. Bismuthi subnitratis, .......................................................... 3ij;
Bismuthi salicylatis, .......................................................... gr. xxxvi;
Elixirs pepsi compositi, .................................................... 3ij;
Misurcre crete, q. s. ad ..................................................... 3ij.

M. Sig.: A teaspoonful every two or three hours.

Special symptoms must be treated as they arise. A mustard plaster on the abdomen for pains, pieces of ice for thirst, etc.

6. Collapse may supervene at any moment. The hot bath or warm mustard bath must be substituted for the cold, the limbs well rubbed; hot drinks given, heated applied externally, stimulants as strychnine and brandy given, and hypodermoclysis.

7. Convalescence. When the patient has reached the convalescing stage, or after the acute stage is passed, there must be a very cautious increase of food to prevent a recurrence of trouble. Peptonized milk, albumen, water, and barley water should be given in teaspoonful doses every few minutes, and a gradual return made to proper feeding, and treating carefully the various conditions as they may arise.

(To be concluded.)

Therapeutic Notes.

Management of Third Stage of Labor.—David Berry Hart, in his recently issued Guide to Midwifery, asserts that no stage of labor is more mismanaged in practice than the third. He dissents from the view that separation of the placenta takes place through a diminution in area of its site owing to the retraction of the uterus, and holds that the separation occurs after the pains, because the now nonvascular placenta does not expand with the uterine wall as it did during the first and second stages of labor. Such a mode of separation is actually appreciable in placenta previa, where, when the placental site in the lower uterine segment expands, separation at once takes place.

The assertion holds good, according to this, that the obstetrician who squeezes the uterus to separate the placenta is making a mistake. The uterus should be grasped, but pressure should not be exerted unless there is some necessity for it. When a good pain comes on, it need not be reinforced, though if the pains are weak, it is right to strengthen them and excite a stronger contraction with the hand. Nothing is worse, according to Hart, than squeezing the uterus unduly during a pain, or hurrying up the next contraction by manipulation between the pains. The only reult
is premature inertia and the risk of expulsion of the placenta and membranes minus a part of them.

An important time in the third stage is when the uterus lessens in bulk, indicating that the placenta has become separated and expelled into either the lower segment or the vagina. In the former case it shows as a projection above the pubes. It is then that downward pressure of the hand in the axis of the brim will express, if necessary, the placenta and membranes. If the separation is complete, very little pressure is required to do this. When the placenta is coming out of the vulva it should be received in the attendant’s hand, and the possibility of the membranes being adherent to a slight or marked degree considered. The attendant should see that the uterus is firm and have the nurse take his place in grasping it while he examines the placenta and membranes to ascertain if they are intact.

Uses of Tincture of Iodine in Ophthalmological Work.—Jacqueau, in Lyon médical for April 27, 1913, points out that tincture of iodine, appropriately employed, is by no means as irritating to the eye as one might suppose, but constitutes a most excellent antiseptic agent in eye work. He found that an aqueous iodine solution presents no advantage over the tincture, but on the contrary seems to possess less penetrating power.

In long standing glandulociliary blepharitis, with crusts and ulcerations, the effects of a few careful applications of the tincture at the roots of the lashes are superior to those obtained with yellow ointment. Whenever iodine is used on or near the eye, however, it is necessary first to instill one or two drops of a three to five per cent. solution of cocaine into the conjunctival sac. This will effectually prevent local irritation and lacrimation.

In traumatic corneal ulcers with incipient infective manifestations tincture of iodine is deserving of widespread use, as it often arrests the morbid process and in the other instances, will so delay its progress as to permit of ultimately saving the eye. After coacervation, and with the lids held apart with the fingers, the tincture should be applied to the affected area by means of a narrow wisp of cotton twisted on the pared end of a matchstick. The patient should be required to fix his gaze on a distant point during the procedure and the lids should be held apart a few seconds after the application, to allow the tincture to dry on without becoming mixed with the lacrymal fluid. Under these conditions, no pain results, there is practically no diffusion of the drug into the healthy tissues. In severe cases the procedure may be repeated without hesitation, daily or even twice a day.

Jacqueau also advises the use of iodine in operative work on the globe and cornea, especially in the cataract operation. On the day before, and where there is particular fear of complications, several days before the operation, the tincture should be carefully painted on the lid margins. This is to be repeated immediately after the operation, and in addition, a little of the tincture should be applied over the line of the corneal incision. While the fact that this procedure was followed by the author in thirty-seven cases of cataract operation without a single case of infection proves nothing, the results seemed superior in this series of patients to those generally obtained, in that the eyes were regularly found quiescent and free of all irritative redness at the first dressing, and healing appeared to take place more rapidly than usual in the majority of cases.

Use of Emetine in the Treatment of Intestinal Hemorrhage.—Valassopoulou, in Bulletins et mémoires de la Société médicale des hôpitaux de Paris, May 22, 1913, reports the case of a woman twenty-eight years old, suffering from alternate constipation and diarrhea, abdominal pain and bloodstained fecal discharges, but without teneurism, in which, after the ordinary treatment for dysentery had failed to yield much benefit, a subcutaneous injection of one third grain (0.02 gramme) of emetine was given as a matter of experiment, though no atrembe could be found in the stools. Within a few hours after the injection the bloodstained evacuations, previously constantly occurring to the number of eight or ten daily for two months, were completely and apparently permanently arrested. Two or three more injections of emetine were given on the succeeding days. At this time, rectal palpation revealed the presence of a firm tumor in the rectal wall, and later another—the primary—tumor, higher up, in Douglas’s cul-de-sac. The case was thus one of rectal carcinoma in which emetine arrested the intestinal hemorrhages.

Treatment of Migraine.—Andrist, in the St. Paul Medical Journal for March, 1913, states that he has found of some benefit in migraine the treatment advocated by Lorand, consisting in the inhalation of an irritating snuff, which by exciting a profuse flow of nasal secretion, draws blood away from the vessels of the dura and pia. One of the snuffs recommended by Lorand is formulated as follows:

\[ \text{R} \]

- Menthol, \ldots gr. viiss (0.5 grammes).
- Acidi boricici, \ldots gr. xv (1 gramme).
- Radicis iridis, \ldots .
- Sacchari lactis, .

- M. Liquid.

Other measures to relieve pain are practically worthless—unless one resorts to morphine or its derivatives. In very nervous and irritable patients the bromides may have their place and are largely used, as are the coal tar products. Often, however, these patients cannot well stand the coal tar drugs. Disorders of the nose or accessory sinuses s. errors of refraction, or muscular strain, should be corrected, when present.

Lohman found that an attack could be cut short by massage of the nape of the neck, precisely at the insertion of the muscles into the occiput, while Andrews recommends dietetic restrictions.

Treatment of Asthma.—Comby, in Monde médical for July 15, 1913, is credited with the following formula for the administration of arsenic to asthmatic children:

\[ \text{R} \]

- Soda arsenatica, \ldots gr. 1/2 (0.02 grammes).
- Potassii bromidii, \ldots gr. viiss (0.5 grammes).
- Syrpi aurantii flor. \ldots 3i (30 grammes).
- Aquae destillatae, \ldots 3ii (60 grammes).

- M. Sig.: Three teaspoonfuls a day.
THE DANGERS OF PITUITARY EXTRACT IN OBSTETRICS.

Pituitary extract has recently found considerable favor among obstetricians, its oxytocic properties having proved in general so marked as to rival and in some instances exceed those of ergot. The precise field of its application, however, and its relative value in comparison with the last named drug, constitute a problem which is still sub judice. Not to be overlooked in this connection are the elements of danger which the use of pituitary extract undoubtedly entail.

The fetal heart sounds were observed by Nagy (Zentralblatt für Gynäkologie, March 9, 1912) to become markedly decreased; Sapaeth (Ibidem, February 1, 1913) recorded a death from this cause, the newborn living but one half hour after birth. In the mother, tetanoid contractions were observed by Mahovský (Rouisky Vratch, October 20, 1912) while Hauch and Meyer (Hospitalstidende, April 2, 1912) refer to two deaths which seemingly were due to the induced abnormally high blood pressure. Of special interest in this connection were the observations of Edgar at the last meeting of the American Gynecological Society (see our issue of July 19, 1913). While the drug has usually been found to produce powerful intermittent uterine contractions, Edgar called attention to the fact that these theoretically intermittent contractions approached practically, in the face of resistance, a continuous character, and must therefore be reckoned with as capable of introducing danger in the use of the drug. In the first stage of labor, full and even small doses of pituitary extract were observed by him to produce compression of the fetus sufficiently prolonged to cause its death, premature placental separation, and rupture of the deeper portion of the cervix. Among thirty-nine cases of inertia in the first and second stages of labor under Edgar's observation, two, and probably four, stillbirths resulted from the administration of pituitary extract before complete dilatation of the os. The significance of these facts is given further emphasis when it is realized that the degree of action of the extract is very uncertain, a quantity as small as one half the dose commonly employed having at times caused uterine contractions of such power and duration as to render rupture of the organ imminent and imposing recourse to anesthesia in order to relax it. Under these conditions one cannot but agree with Doctor Edgar's conclusion that pituitary extract should never be administered to overcome inertia in any stage of labor, unless anesthesia can be immediately instituted and preparations have been made for immediate operative delivery, if this should be required.

Comparing the extract with ergot, one finds even in great activity of the former drug an element of advantage, for in cases where ergot fails to contract the uterus satisfactorily the addition of the extract introduces a possibility of turning the tide in a favorable direction. On the other hand, among eighteen cases in which pituitary extract was given just after the termination of the third stage, to control post partum hemorrhage, the result of insufficient uterine contraction, Edgar found the drug unreliable and not so positive in its action as ergot, only six of the cases showing, after its administration, contractions sufficiently marked to preclude the necessity of adding other adjuvant measures to arrest hemorrhage or of actually packing the uterus.

On the whole, the advice of Rieck (Münchener medizinische Wochenschrift, April 9, 1912) that the serious complications which may occur in the use of pituitary extracts during labor are such as to limit its use to hospitals, where prompt medical service is available, seems to merit serious consideration.

A BUREAU OF DEPORTATION FOR ILLINOIS.

We note with a good deal of interest the recent passage of a law by the Legislature of Illinois authorizing the establishment in that State of a bureau for the deportation and expatriation of its
alien insane, similar to the one in existence in the State of New York.

This again brings to the fore the vital problem of the increase of insanity and mental defectiveness in this country through immigration, and it is a healthy sign of the times when the various States are taking cognizance of this. No one who is at all acquainted with the excellent work of the United States Public Health Service can fail to appreciate the tremendous value to the nation of the work of its officers in the medical inspection of arriving aliens. At the same time those who are familiar with the subject of psychiatry will readily appreciate the absolute impossibility of detecting all the insane aliens, or anything approaching this, at the time of their arrival in this country. Such an ideal state of affairs would be out of the question even under the most favorable conditions and with the most excellent working facilities, let alone under conditions such as exist for instance at Ellis Island. Some of these difficulties have been pointed out in a recent issue of The Survey by Surgeon E. K. Sprague, of the Public Health Service. When we remember that according to this author the ridiculous sum of eight and a fraction cents a head was expended by the federal government during the fiscal year of 1912 for the medical examination of each alien arriving at the port of New York, it is small wonder that the provisions of the immigration laws cannot be properly carried out. And just so long as proper facilities for the enforcement of the law will not be furnished by the federal government the country will continue to be flooded with undesirable aliens.

States like New York and Illinois, which are burdened most by the influx of alien insane and defectives, have tired of calling on the federal government for relief, and have decided to take matters into their own hands by the establishment of bureaus such as outlined above.

The State of New York was the pioneer in this respect, and that the results have justified the experiment is amply illustrated by the report of its Bureau of Deportation for 1912. According to this report a total of 1,771 insane persons were deported from the State of New York during 1912: what this means to the State in dollars and cents can readily be computed when we keep in mind that, conservatively estimated, the cost of each one of these insane to the State is about $275 per annum, and the average life is estimated at ten years.

When we consider, however, the effect upon the mental health of the nation which an unrestricted influx of alien insane must eventually have, the financial phase of this problem really fades into insignificance.

The work contemplated by the Bureau of Deportation is of the nature of field work, and in connection with the immigration inspection work of the officials of the United States Public Health Service, it is hoped, will eventually solve the highly important problem of the alien insane.

OLD WARSHIPS AS SANATORIA.

A resolution, offered by Dr. S. Adolphus Knopf, of New York, and adopted unanimously at the Fourth International Congress on School Hygiene, held in Buffalo, N. Y., in August (see page 501 of this issue) endorses the proposal to use old, discarded battleships as sanatoria or preventoria, and expresses the hope that our government will follow the example set by the Italian secretary of marine, who authorized three old warships of that nation to be converted into floating sanatoria for the treatment of children suffering from tuberculosis. The plan should be peculiarly satisfactory, because by such means most of those tuberculous children would be cured. In children the disease does not manifest itself so much in the lungs, but much more often in the bones, joints, and glands. For such cases the sea air is most beneficial; besides, as only the sputum of consumptives carries the contagium, and as such children expectorate very little, or not at all, there would be practically no danger of their spreading the disease. The French government evidently appreciated the importance of these points several decades ago, when, for the care of the tuberculous, scrofulous, or rachitic children of its poor, it established large and excellently equipped hospitals on its seacoast, where these puny sufferers are assured of the benefits of the sea air, ozone, and of the healing iodine and other halogen salts liberated from the breaking waves. In addition, appropriate diet in generous amounts, careful nursing, and adequate medical care of their "white swellings" and other ailments are furnished. Hence, instead of early death, or what is worse, the prospect of growing up weaklings, cripples, or hunchbacks, most of these children acquire stronger constitutions and have a happy and useful future assured them. The government in this way reclaims many future worthy and virile citizens, who would otherwise be lost to it. Our Sea Breeze, on Coney Island, New York, was modelled after one of those French hôpitaux maritimes for tuberculous children. Of the same nature is also the work of St. John's Guild, which summer after summer, for many years past, has been working its life saving wonders for the metropolis.
The importance of all these facts becomes apparent when we realize that, as stated in the preamble concerning the use of discarded battleships, nearly one million tuberculous children are attending school in the United States, while there is hardly accommodation for 1,500 to receive instruction in the open air.

NEUROSES OF DUCTLESS GLANDS.

At the fourteenth annual meeting of the American Therapeutic Society John C. Hemmeter, of the University of Maryland, presented an address on the Hypertonicity and Hypotonicity of the Vagus and Sympathetic Nervous System, and the Neurochemical Synergism of the Normal Body and Its Suggestions for Physiological Therapeutics, in which he introduces what he regards as a new doctrine of pharmacodynamic action, and the first description of internal secretory gland neuroses.

It is not possible at this time to take up the former of these, but we will endeavor to give, briefly, some idea of the latter. The elective affinity of chemical substances such as atropine and pilocarpine for certain parts of the vegetative nervous system has been designated by the term tropism, but Doctor Hemmeter prefers the more precise one, pharmaco-tropism. Two fundamental concepts must be borne in mind in interpreting the complex pharmaco-tropisms: First, that there is a diffuse dissociation of the individual effects of the neurotropic substances; second, that when the tonic innervation, the increased excitability of the vegetative nervous system, has been found to exist, it need not come to expression in all the organs of response. In other words, these various organs in single individuals react in a different manner to the same stimulus.

In referring more particularly to the thyroid, Doctor Hemmeter states that it has been shown by Asher, Flack, and other investigators that this gland can be influenced by fibres in the superior laryngeal nerves. Moreover, these special fibres are of sympathetic origin. We are now learning with growing certainty, he says, that we can have secondary secretory neuroses of the thyroid simulating Basedow's disease, but due to a primary disease of these secondary secretory fibres. The thyroid is just as much dependent upon and controlled by the neural system as are the salivary glands, and therefore we have a right to believe that there are thyroid neuroses, just as there are gastric neuroses. This is rendered all the more probable by the fact that clinical cases with all the phenomena of Graves's disease are met with, which have not been relieved by thyroidectomy, and in which parts of the removed thyroid were found normal; there being no hyperplasia of secreting vesicles, no liquefaction of colloid material, and no small round cell infiltration.

As is well known, the nervous theory of Graves's disease, in which, as stated by Putnam, of Harvard, "irritation of the sympathetic system is considered the exciting factor" is not a new one, a fact which applies also to the "fright complex" theory of Mackenzie. Laignel-Lavastine, Frankl-Hochwart, and others have also associated neuroses with the ductless glands. However, Doctor Hemmeter's views will do much to attract attention to a neglected though promising field, and doubtless contribute to our knowledge.

CHAULMUGRA OIL IN LEPROSY.

Dr. Victor G. Heiser, chief quarantine officer and director of health for the Philippine Islands, publishes a very interesting note regarding the apparent cure of two lepers in Manila in the Public Health Reports for September 5, 1913. The two patients who had been confined to the San Lazaro Leper Hospital on account of leprosy have been pronounced apparently cured and discharged from that institution on probation. The first case was that of a male Filipino, aged twenty-seven years, who had been at the hospital for four years. On admission the patient clinically showed thickened reddish spots on the nose, and thickening and discoloration of the lobe of the right ear, while scrapings made from the lesions showed lepra bacilli. Vaccine treatment, given at intervals for one year, produced no change. As chaulmugra oil by mouth was followed with nausea, although improvement was evident, chaulmugra oil combined with oil of camphor and resorcin was given hypodermatically for about six months, when the lesions had disappeared and leprosy bacilli were not found microscopically. But the hypodermatic use of chaulmugra oil was continued for two more years, during which time examination was always negative. The patient was then discharged on probation. The second case, a Filipino woman of twenty-two years of age, is very similar. Doctor Heiser, in conclusion, states that it is not known whether the vaccine treatment had any influence in the cures. There are at the present time a number of other patients at the San Lazaro Leper Hospital in whom examinations have been negative for a period of twenty-two months, and who, upon admission, presented more marked evidences of leprosy than the cases mentioned above, yet they received only chaulmugra oil either by mouth or hypodermatically, or in both ways.
DIAGNOSIS AND TREATMENT OF FRACTURES INVOLVING THE KNEE JOINT.

J. P. Blake says in the *Annals of Surgery* for July, 1913, that the five principal traumatic bone lesions involving directly, or indirectly, the knee are influenced less than might be expected by the fact that they invade the largest joint in the body. Trauma affecting the knee joint, if sufficient to produce fracture, causes fracture of the patella most frequently, of the femur next in order, and of the tibia least often; in patients under twenty years such trauma usually causes separation of the lower femoral epiphysis. With the exception of sepsis, the other complications added to fractures in this region are: (a) Greater difficulty in maintaining position of the fragments; (b) greater limitation of motion after union has taken place; (c) in certain operative cases, an added danger, that of invading a joint with a solid body. The indications for treatment are similar to those applicable to other fractures except that nonabsorbable materials should not be used within the limits of the knee joint unless it is absolutely unavoidable, nor should the immobilization continued for a period longer than is advisable in fractures not involving joint cavities.

**News Items.**

**Association of Military Surgeons of the United States.**

The annual meeting of this association will be held in Denver, Colo., September 16th to 19th. Surgeon W. C. Braisted, United States Navy, is president, and Colonel Samuel C. Eaton, of Chicago, secretary.

**Medical Society of the State of Pennsylvania.**

This society will meet in annual session in Philadelphia on September 22d, 23d, 24th, and 25th, under the presidency of Dr. Lewis H. Taylor, of Wilkes-Barre, Pa. An excellent program has been prepared, and invitations point to one of the most successful meetings ever held by the association.

**Curtin Alumni Scholarship.**

The Philadelphia Alumni Society of the Medical Department of the University of Pennsylvania has decided to provide for funds to endow a scholarship which it is planned to establish in memory of the late Dr. Roland G. Curtin. Those who would like to show honor to the memory of Doctor Curtin by contributing to the fund may remit to the treasurer, Dr. Lewis H. Adler, Jr., 160 Arch Street, Philadelphia.

**Meetings of Medical Societies to Be Held in Philadelphia during the Coming Week.**—Monday, September 13th, Philadelphia Clinical Association and the Episcopal Hospital Clinical Society; Tuesday, September 16th, West Branch of the County Society, North Branch of the County Society, and the Philadelphia Laryngological Society; Thursday, September 18th, Northeast Branch of the County Society; Friday, September 19th, Southeast Branch of the County Society.

**The Lane Medical Lectures.**

The fourteenth course of Lane medical lectures was delivered in Lane Hall, Medical Department of Leland Stanford, Jr., University, on the evenings of September 3d, 4th, 5th, 8th, and 9th, by Sir Edward A. Schaefer, professor of physiology in the University of Edinburgh. The topics of his lectures were as follows: September 3d, On Internal Secretion in General; September 4th, On the Thyroid Glands; September 5th, On the Mammalian Glandular Apparatus; September 8th, On the Pituitary Body; September 9th, The Influence of Internal on Other Secretions. These lectures were founded in 1896 by the late Dr. Levi Cooper Lane, and are given free of charge to medical subjects by men distinguished at home or abroad for their work in either medicine or surgery, and are intended for medical students and the medical profession at large.

The Cumberland Valley Medical Society.—At the annual meeting of this society, held in Hagerstown, Md., on September 4th, the following officers were elected: President, Dr. E. Roberts Plank, of Carlisle; vice-president, Dr. E. Tracy Bishop, of Smithsburg; Dr. E. S. Berry, of Shippensburg; Dr. John G. Gordon, of Chambersburg; secretary, Dr. John J. Coffey, of Huntingdon; assistant secretary, Dr. J. Royser Lambkin, of Hagerstown; Dr. R. M. Shipley, of Carlisle; Dr. E. D. Palmer, of Green Castle; treasurer, Dr. H. C. De Vilbiss, of Chambersburg. It was decided to hold the next annual meeting in Cumberland County, Pa.

**American Electrotherapeutic Association.**

At the twenty-third annual meeting of this association, held in New York on September 26th, 27th, and 28th, the following officers were elected to serve for the ensuing year: President, Dr. Charles E. Blake, of Providence, R. I.; vice-presidents, Dr. Albert C. Geyser, of New York, Dr. Frank B. Granger, of Boston, Dr. John D. Torbett, of Martins, Texas, Dr. William L. Clark, of Philadelphia, and Dr. Frederick T. Plank, of Roanoke, Va.; treasurer, Dr. G. T. Henel, of New York (reelected); secretary, Dr. J. Willard Travell, of New York (reelected); registrar, Dr. Frederick M. Law, of New York (reelected).

**The Harvey Society Lectures.**

Among the lecturers of the Harvey Society for the current year are the following: Professor A. D. Waller, director of the Physiological Laboratory of the University of London; Dr. Adolf Schmidt, professor of medicine, University of Halle; Dr. Charles V. Chapin, of Providence, R. I.; Dr. Rufus I. Cole, of the Rockefeller Institute; Dr. George Howard Parker, professor of zoology, Harvard University; Dr. Victor C. Vaughan, professor of hygiene and physiological chemistry, director of the histological laboratory and dean of the medical faculty of the University of Michigan; Dr. Sven G. Hedin, professor of physiological chemistry, University of Upsala; and Dr. J. R. MacLeod, professor of physiology, Western Reserve University. The course will be inaugurated on October 4th, with a demonstration before the New York Academy of Medicine, by Doctor Waller on the Origin and Scope of Electrocardiography.

**Ohio State Medical Association.**

The sixty-eighth annual meeting of this association was held at Cedar Point, on September 2d, 3d, and 4th, under the presidency of Dr. J. C. M. Floyd, of St. Marysville. An interesting feature of the proceedings was the adoption of a new constitution, the most important changes being the combination of the offices of secretary and treasurer, the creation of the office of auditor, the elimination of the powers of the council. A committee was appointed by the surgical session to investigate the question of industrial injuries. Dr. Charles F. Hoover, of Cleveland, delivered the address in medicine, and Dr. John F. Erdmann, of Columbus, the address in surgery, on the subject of Acute Pancreatitis. Dr. George Fackler, of Cincinnati, was elected president; Dr. J. H. J. Upham, of Columbus, president-elect; Dr. C. D. Selby, of Toledo, secretary-treasurer, and Doctor Upham, managing editor of the State Journal. Dr. B. R. McClelland, of Xenia, Dr. John A. Thompson, of Cincinnati, and Dr. R. H. Bishop, Jr., of Cleveland, were elected members of the Committee on Public Policy and Legislation.

**Additions to the Faculty of the University of Illinois.**

The following appointments to the faculty of the University of Illinois, Chicago, have been announced: Dr. Albert Chauncey Eyleshym, dean of the St. Louis University Medical School, to be professor of anatomy and head of the department of anatomy; Dr. Richard Rupert, of Chicago, instructor in anatomy; Dr. George P. Dreyer, of Chicago, professor of pathology and head of the department of physiology in the school of medicine; Dr. Kermit F. Fann, of Chicago, professor of pharmacology; Dr. Edgar Grim Miller, of Columbia, Pa., Dr. J. Craig Small, of Chambersburg,Pa., and Dr. H. N. Walker, of Harrisburg, Pa., assistant professors of physiological chemistry; Dr. Fred B. Hoyes, of Chicago, professor of orthopedic surgery and the head of the department of surgery; Dr. H. C. Olund, of Chicago, professor of materia medica and therapeutics; Dr. Louis Schultz, of Chicago, assistant professor of oral surgery and pathology; Dr. Louis E. Bake, of Chicago, professor of clinical medicine; Dr. Edward F. Van Buskirk, of Chicago, professor of the surgical practice of dentistry; Dr. S. B. Smarr, of Chicago, assistant professor of prothetic technics; Dr. Henry C. Lee, of Chicago, instructor in dentistry; Dr. F. S. Bernard, of Chicago, instructor in prothetic dentistry.
DEUTSCHE MEDIZINISCHE WOCHENSCHRIFT.
July 3, 1913.

The Use of Cathartics and Anastaletics for Children.—W. Birk explains the cause of general intestinal disturbances in infants as originating in overfeeding. All feedings bear overfeeding for a while, after a little they grow restless and vomit; the body's weight becomes stationary; tympanites, flatulence, more frequent green stools appear. The feces are of a mixed color, slimy, containing white specks of undigested food throughout. In these cases the author discontinues all food and gives only tea sweetened with saccharin. No cathartics nor anastaletics are used. Within twenty-four hours the intestinal tract is empty and fermentation is at an end. There is now added to the tea a light sustaining diet, usually strained gruel, for the next two days and thereafter milk is added in slowly increasing quantities. Light disturbances are easily cured by this method; in the more severe forms, however, this treatment will not suffice. Finkelstein's milk of albumin is best prepared by the chemist, but may be made at home as follows: One litre of milk, adding remet; the resulting whey is not used, but replaced by a half litre of water; this mixture is rubbed through a fine mesh sieve until thoroughly disintegrated; a half litre of buttermilk is added. We have now one litre of milk containing the milk sugar of a half litre of milk, the fat of one litre and the albumin of one and one half litres of milk. This preparation is used for the more severe forms of gastrointestinal disturbances arising from overfeeding. It is considered the best anastaltic remedy in acute intestinal disturbances from this cause. Its use, in very gradually increasing quantities, is continued for one month, when the child resumes its usual diet.

Therapeutic Action of a New Codeine Derivative, Paracodeine.—W. Dahl says that paracodeine fills a gap between the codeine and morphine groups. As a result of experience the author asserts that when paracodeine is given, like codeine, in small doses, it often acts with more intensity than codeine. Compared with codeine the new remedy has a greater sedative power. For certain uses this remedy will advantageously replace even morphine. No unpleasant aftereffects, any more than with the codeine preparations, have been observed. The new preparation is a hydrated codeine, soluble in warm water. The dose generally used was from 0.025 to 0.03 grammes.

Salvarsan Treatment of Progressive Paralysis.—Raecke asserts that paralytics suffer no ill effects from salvarsan when the remedy is carefully used. It seems, on the contrary, to increase the length of the remissions and to prolong life. Whether the noted improvements are due, solely, to salvarsan, and whether the cure is a permanent one, can only be decided by years of observation. At all events we are to-day justified in recommending a trial of the salvarsan cure during the acute stage of suffering and for cases having an otherwise bad prognosis.
Obstetric Significance of Underdevelopment.—E. Vogt believes: 1. That hypoplastic individuals need close attention during the lying-in period, especially after the birth of the child. 2. Even very moderate loss of blood should receive close investigation, because with true oligemia a relatively small loss of blood endangers life. 3. Operative procedures are only to be resorted to under urgent indications because hypoplastic individuals do not bear an anesthetic well, and they are subject to a continuous parenchymatous loss of blood.

July 17, 1913.

Studies on Aleucocytic Animals: The Presence of Lymphocytes in the Serous Cavities.—Lippmann and Plešek present the results of their experiments as follows: The animals were first rendered aleucocytic by injections of thorium x, given intracardially. Thus in aleucocytic animals there results: 1. A purely monocytic pleural exudate in which are found all endothelial cells changing over to such as resemble small lymphocytes. 2. No protective cells are drawn toward an inflammatory muscle centre. Only muscle necrosis is seen. 3. Therefore the small lymph cells are neither hemogenous nor of the adventitious cell variety. They are derivatives of the serous endothelia. 4. The small lymphocytes found in the fluid of the cerebrospinal system and in the pleural exudate are also remnants of serous endothelia. The presence of lymphocytes in serous exudates is only an indication of a chronic inflammation of the serous membrane; there are no specific antigens. 5. The pleura and peritoneum are biologically different because in the peritoneum of aleucocytic animals polynuclear cells are found, while in the pleura only monocytes are produced during an inflammatory process.

Clinical Examination of the Condition of the Blood after Total and Partial Removal of the Thyroid Gland.—P. Reckzech, as a result of experiments on dogs, sums up as follows: In dogs removal of the thyroid resulted in secondary anemia in about a week. The condition of the white blood corpuscles pointed to an impairment of bone marrow function, the same as in anemias from blood poisoning. The conditions existing in patients suffering with Basedow's disease and myxedema agree with these experimental results. The presence of relative lymphocytosis was especially frequent.

July 21, 1913.

Thymus Gland.—K. Basch concludes from his experimental examination of the biology of the thymus that it has an influence on the growth and development of bones and on the excitation of the nervous system, as well as on the control of the pupillary apparatus of the eye; and that it is in close relation with internal glandular secretion, especially with the thyroid and the glands of the reproductive apparatus. Many anatomical and clinical phenomena point to a connection with the lymphatic system.

Treatment of Articular Rheumatism with Electargol.—Schönfeld states that the compounds resulting from the chemical union of colloids with certain metals made good remedies in the treatment of infectious diseases. Electargol is such a remedy, used in many forms of rheumatic affections of a bacterial and septic character. The blood and tissues are freed from bacteria and their toxines. Not all patients with articular rheumatism may be treated with electargol; but only those who are very ill and have not responded to the usual treatment with salicylates. The author reports ten patients of this type who were suffering from an acute attack. They were first treated with salicylates and baths without success. Treated with electargol, five c. c. were given on the first day, and ten c. c. on the second day, by hypodermatic injections made in the gluteus medius muscle. The injections gave rise to no pain. The rheumatic pain was markedly relieved by the following day and the course of the disease greatly shortened. The ten patients were under treatment from June, 1912, to January, 1913.

July 31, 1913.

Ulsanin.—R. Mandl says that the use of hydroiodoborate (ulsanin) shortens the time of healing in lupus and scrofulous granulating skin affections. The loss of tissue is less and the scars are not as apparent. It is an admirable remedy for disinfecting freshly infected wounds, in that nascent iodine and oxygen are given off without poisonous results. Its effects are rapid and thorough. After the removal of necrosed tissue, the pus quickly diminishes. On account of the rapid and clean healing there is a great saving in dressings. Being nonpoisonous it may be used for wounds of the scalp and abdomen.

Zentralblatt für Gynäkologie.

July, 1913.

Kraurosis and Squamous Epithelioma.—Teuffel reports a case in which these two conditions occurred independently. The kraurosis involved primarily the clitoris and to some extent the labia majora. Cancer formation was also present in the deeper layers of the adjacent epithelium, the surface cells of which were intact.

True Prophylaxis of Cancer of the Uterus.—Bösi believes that the development of cancer of the cervix can be greatly inhibited if, by means of slight operations, the original chronic ulcer be removed. He feels certain that in most cases the cause of cancer of the uterus is to be found in chronic inflammation; that this condition is not bacterial in origin, but arises as a result of histological disturbances.

Pregnancy Following Acromegaly.—Kaldy shows a case of a woman, twenty-two years of age, in whom symptoms of acromegaly began to develop. On account of the neutralizing effect of ovarian secretion upon that of the pituitary body, the author administered ovarian extract. Under this treatment she improved very much. In the course of some three months she became pregnant. The treatment was then discontinued on the basis that the ovaries were taking on their normal function, and, consequently no more extract should be administered lest it would interfere with the action of the pituitary body.

A Case of Ovarian Abscess Following Labor.—In a case reported by Ohmann, chills and fever developed in the patient, one week after the delivery of a dead baby. At the operation there was found
an ovarian abscess about the size of a goose egg. Bacteriological examination showed the presence of streptococci in pure culture, although no bacteria could be demonstrated in smears. On account of the general belief that such lesions are really abscesses of the corpus luteum, careful search for lutein cells was made. None were found, but their absence could well be explained as being the result of degenerative processes following the infection.

Unusual Fertility of Women.—Neugebauer briefly reviews some of the instances of unusual fertility and reports a case in his own practice—a woman who had nine living babies, thirteen abortions and one extraterine pregnancy.

CENTRALBLATT FÜR ALLGEMEINE PATHOLOGIE UND PATHOLOGISCHE ANATOMIE.

July, 1913.

The Relationship between Eclampsia and Tetany during Pregnancy as a Result of Experimental Parathyroid Insufficiency.—Massaglia removed two of the parathyroid glands from young dogs without the development of any symptoms of parathyroid insufficiency. Later when the animals became pregnant, and while nursing their young, attacks of tetany appeared. According to the author these outbreaks occurred at a period identical to that when eclampsia appears in women.

LYON MÉDICAL.

August 10, 1913.

Syphilitic Aortitis with Insufficiency of the Left Ventricle.—L. Gallavardin asserts that in those cases of syphilitic aortitis in which the diagnosis of the condition is difficult owing to the absence of symptoms specially referable to the aorta, high vascular tension with latent or evident nephritis, and on the other hand, cardiac weakness with symptoms of circulatory insufficiency, are significant accompanying conditions. In the second of these forms, illustrated in two cases reported by the author, syphilitic myocarditis alone is not sufficient to explain the marked ventricular hypertrophy observed. In obscure cases of circulatory affection the possibility of a syphilitic aortitis should be remembered.

PARIS MÉDICAL.

August 2, 1913.

Acute Cerebrospinal Meningitis with Cerebellar Manifestations.—A. Coyon and E. Joltrain report the case of a man, seventy-five years of age, who was admitted to a hospital presenting evidence of meningal disturbance which lumbar puncture showed to be due to acute meningococcic cerebrospinal meningitis. There was a history of traumatism to the occiput, followed by headache and vertigo, and on the eighth day by a chill, fever, contractures, vomiting, and constipation. Incoordination of cerebellar origin gradually developed, together with slight horizontal nystagmus. Delirium, slight bradycardia, coma, and death followed. The autopsy showed purulent inflammation involving especially the pons, medulla, and cerebellum, and extending deeply into the latter.

Treatment of Complications of Gonorrheal Infection.—L. Cruveilhier reports cases of acute gonococcal metritis and salpingitis, gonorrhreal rheumatism of the arthralgic, acute arthritic and chronic forms, and acute gonococcal orchitis, in which prompt relief of pain, inflammatory swelling, and other manifestations was obtained by the giving of repeated injections of Besredka's sensitized antigenococccus virus vaccine.

PRESSE MÉDICAILE.

August 9, 1913.

Case of Erythema with Unusual Manifestations.—A. Chauffard and J. Troisier report a case of Vaquez's disease (chronic cyanosis with splenomegaly) in which, five months before death, there appeared signs of portal obstruction, with marked ascites, prominent collateral circulation, and hemorrhoids. The erythema was for a time completely removed by the administration of sodium citrate. At autopsy there were discovered splenic phlebitis, gastroepiploic thrombosis and a certain amount of sclerosis of the liver. The thrombosis was probably due in part to infection, aggregations of polymorphonuclear leucocytes being found.

Spontaneous Autoplasty through Gradual Extension of Tissues.—H. Morestin refers to the fact that when the integument is destroyed on the flexor aspects of joints, considerable difficulty is often experienced in covering it with skin from other localities to obviate subsequent retraction and loss of function. In the treatment of these cases he has utilized a new principle, viz., that healthy skin can be stretched almost indefinitely when subjected to repeated or gradual traction. The aim is to avoid cicatrical tissue as much as possible, such tissue being responsible for the deformity not uncommonly met with. The technic consists merely in placing the limb in such a position that the healthy skin borders can be sutured together without strain, taking every step necessary to secure primary union, without regard to the faulty posture and then, after healing is complete, utilizing every means to stretch out the integument and restore motion at the joint, especially through exercises carried out by the patient himself. The author presents histories and photographic reproductions of six cases in which large open surfaces left after operations for, respectively, verrucose tuberculosis of the anterior aspect of the forearm, secondary cancer of the inguinal region, cancer of the forearm over the site of a former burn, large scar of the shoulder and scapular region following cold abscess, inguinal sarcoma, and annular scar of the wrist after a burn, were successfully covered, with unusually rapid and complete return of function by the method described.

LANCET.

August 27, 1913.

The Use of Radium in Malignant Disease.—Robert Abbe of New York draws his conclusions from observations made upon 750 individual cases. Many forms of tumors which are not malignant respond to the use of radium in a most satisfactory and prompt manner. Epithelioma of the skin can be cured permanently with radium, and perhaps better than by any other known agent, and with the least scar. The worst types of cancer—of the breast
or uterus in women, and of the stomach, esophagus, tongue, and rectum—usually show prompt and marked amelioration under large doses of radium, but ultimately the disease gains headway, and the temporary gains are lost. Giant cell bone sarcoma can be controlled promptly and certainly by radium. In no case of pure myeloid sarcoma has radium failed to cause retrogression and arrest of the condition. It may be concluded: 1. That there is an undoubted retrograde degeneration of malignant cells under the correct dose of the gamma rays from radium. 2. That the effective use of the drug lies in the application of a large enough amount to avoid the stimulant action of small doses at close range. 3. The alpha and short beta rays may be removed by filtration through lead. 4. Under such filtration a much longer time is required for the gamma rays to act than when the other rays are eliminated by what may be termed "distance filtration." In practice one and one half inches seems to exclude most of these, permitting free and instant play of the gamma rays without the delay of passage through lead. 5. Cross firing is necessary for the best results.

The Preventive and Curative Treatment of Industrial Lead Poisoning.—Thomas Oliver has been able to show on animals that the elimination of lead through the skin can be accomplished by immersing the posterior extremities in one bath, and the anterior in another while the baths are connected with the positive and negative poles of an electric circuit. By this means he has been able to restore paralyzed animals to a state of almost perfect health. It is a method of deionization. He has employed a modification of this method in the treatment of men in lead industries with the most phenomenal success. Often the lead line will vanish in two or three treatments, and complete recoveries are proportionately rapidly brought about. For men a series of arm and leg baths are arranged so that more than one patient may be treated at the same time. The positive pole is placed in the foot bath and the negative in that for the arms. Between these two poles, which are of pure aluminum, a current of sixteen volts with from twenty to forty milliamperes is passed through the patient's body. There is no unpleasant sensation if the current is introduced gradually by means of a rheostat. The resistance of the bath water is reduced by the addition of common salt. The bath lasts for half an hour and is given daily or every other day.

The Presence of Acetone Bodies in the Urine and Their Clinical Significance.—J. E. Piper reviews some of the older methods of detecting acetone and diacetic acid and calls attention to their lack of delicacy and to their inaccuracy. Then, after describing more suitable methods, he relates the finding of diaceturia in ninety-eight per cent. of all postoperative cases in which open ether was used. His patients were very carefully observed with regard to fasting and all other extraneous factors which might enter to influence the formation and excretion of these bodies. Upon these points he finds that the presence of albumin does not affect the presence of these bodies, nor does the duration of the operation have any influence upon their abundance. Chloroform is less likely to lead to their abundant production than is ether. There is no relation between their amount and the total quantity of urine passed in twenty-four hours. Septic cases produce smaller amounts than nonseptic ones. The longer the abstinence from food the greater the abundance of the bodies, other things being equal. The greatest single influence leading to an abundance of acetone bodies seems to be the neurotic disposition and mental anxiety before the operation. An interesting point in Piper's work is the observation that the administration of sodium bicarbonate, as so commonly recommended, has little or no effect; the use of glucose is of some value, but the administration of twenty-five grains of pancreatin as soon as possible after the operation practically removes all trace of acetone or diacetic acid, and in cases with pre-anesthetic acetonuria its use greatly diminishes the amount present. The reason for this action of pancreatin is not understood.

JOURNAL OF TROPICAL MEDICINE AND HYGIENE.

Observations on Ankylostoma Infection.—E. J. Wyler, after discussing the conditions existing in regard to ankylostomiasis in a certain district of Southern Nigeria, states that without doubt thymol is the most efficient anthelmintic for this disease. While some writers advocate a light or fluid diet on the day preceding thymol treatment, it seems to the author of greatest importance that no food should be given on that day or on the day of administration itself, until at least six hours after the last dose of thymol. He thinks neglect of this precaution has sometimes enabled sufficient fat or oil to gain admission to the intestinal tract to cause the absorption of a toxic dose. When administering thymol in ninety grain doses, it is the author's practice to give six drachms of magnesium sulphate on the afternoon of the day preceding the treatment. On the following morning, the thymol is given in three doses, each of thirty grains, at hourly intervals. In the afternoon magnesium sulphate is again given. The patients are kept recumbent the whole of the morning on which the thymol is administered. Of fifty-seven individuals who received the ninety grain treatment, six, or 10.5 per cent., showed ova in the dejecta one week later. It would therefore seem desirable in routine practice to administer at least two ninety grain treatments.

July 15, 1913.

Malarial Anemia.—J. P. Bates ascertained, through clinical observations in Panama, that after acute initial attacks of malarial fever there occurs a rapid loss of hemoglobin and red blood cells. The hemoglobin loss, in two or three months of irregular fever, may take place to an amount of from forty to fifty per cent. of the normal, and the reds diminish to the extent of from two to two and one half millions to the c. m. After the attack is cut short by treatment the recovery in these blood elements is likewise rapid. In uncomplicated malaria occurring in repeated attacks over a period of from three to six years, the loss of hemoglobin and red cells not only ceases, but tends to increase almost or quite to normal, in spite of repeated recurrences
of fever. In the grave secondary anemias, there are other causative factors besides malaria, viz., first, uncinaria infection, and second, a state of semistarvation, not always from a deficient quantity of food, but on account of its poor nutritive value. With these two factors made to bear their share in the causation of grave secondary anemias in malarial subjects in tropical and other malarious countries, and with kala azar excluded, there is no such thing as a grave malarial anemia persisting over a long period of time, finally to terminate in a distinct entity, "malarial cachexia." The last named term is misleading, serving only to misdirect efforts toward alleviation, and should be abandoned in medical nomenclature.

Cooked Green Vegetables in the Treatment of Acute and Chronic Diarrheas.—Cunningham Wilson says that since 1904 he has been treating all chronic diarrheas and dysenteries that resisted the ordinary treatment with opium and bowel irrigation, with a diet of spinach, turnip greens, and mustard tops with the most gratifying results. He begins by giving a tablespoonful or more of one of these four times a day for a week or two, giving no other food, unless the patient is very hungry, when a little toast or corn bread may be eaten. The first few stools after beginning this diet will show the undigested food, but immediately afterward the movements become normal in consistency, and usually after the second day enemas are needed. Flatulence and tenesmus disappear. Spinach is cooked in the usual way, but a little more thoroughly. Turnip greens and mustard give the best results, but when these cannot be had spinach answers well and is better borne by delicate stomachs. After returning to regular diet the use of these greens for lunch and dinner is insisted on for some weeks. Amebic dysentery is improved, but not permanently, in this way.

The Removal of Adenoids and Tonsils in Children.—A. Coolidge and F. E. Garland say that tonsils should not be removed for trivial symptoms. Tonsilllectomy is not justifiable simply because the tonsils protrude in front of the pillars, nor because they look ragged, nor for occasional sore throat, nor because they contain plugs, nor because the patient is under ether for adenoids, nor for any remote symptoms not of a serious nature, nor to protect the child from indefinite infection, nor for an occasional attack of simple acute tonsillitis. Tonsilllectomy should be looked upon as a serious operation, and therefore not to be entered into unadvisedly or lightly, but reverently, discreetly, soberly, and advisedly. Although the function of the tonsillar ring is not known, it is commonly supposed to aid the child in some way against different infections which threaten him through the open portals of the nose and mouth. It may aid in elaborating acquired immunities to the organisms which it receives into its crypts. Although this view is an argument for conservatism, it is not an argument against removing parts of the ring which are in the way or diseased.

Congenital Hypertrophic Stenosis of the Pylorus, with X Ray Plates.—Charles G. Mixter reports four cases and in conclusion emphasizes these points: 1. An early diagnosis is the most essential factor in lowering the mortality from this disease. 2. The bismuth x ray will conclusively demonstrate the presence of pyloric obstruction. 3. In any case in which careful medical treatment has been unable to check the vomiting and progressive loss of weight, and where a pyloric obstruction can be demonstrated by the x ray, even if the differential diagnosis cannot be definitely made between hypertrophic stenosis and pylorospasm, exploration should be advised. 4. X rays, taken at varying intervals after operation, show the pyloric obstruction to be a permanent condition. 5. In the cases studied spasm was of no importance as a factor in the obstruction. 6. In true stenosis surgery offers the only hope of cure. 7. The infant develops normally after posterior gastroenterostomy.

The Clinical and Pathological Relationships of Hyperplastic and Nonhyperplastic Goitre.—As the result of the studies on this subject which have been made in the surgical clinics, H. S. Plummer finds the following points especially worthy of note: The clinical classification of the cases of goitre, into simple or exophthalmic, or equivalent terms, and the pathological classification of the thyroids removed into those with, and those without, sufficient hyperplastic or hypertrophic changes to characterize the gland; the recognition of toxic goitre heart in a certain proportion of cases which are
not diagnosed exophthalmic goitre, and a less generally well defined idea that the cardiac damage is only one of the manifestations of a general toxicosis; the finding of hyperplastic changes in from seventy to ninety per cent. of the thyroids removed for exophthalmic goitre, and the occasional presence of hyperplasia in glands removed from patients not having a history of notable toxic symptoms.

Reciprocal Relations of the Clinic and the Laboratory in Medicine.—Starting with the statement that the clinic has been under obligations to the laboratory since the time of the first post mortem descriptions of normal organs, and of pathological changes in organs and tissues, T. W. Hastings treats of the indebtedness of the modern medical clinic to the medical sciences, and the practical development of the clinical laboratory. In conclusion he says that if one recalls the progress of clinical medicine during the past thirty years, one will appreciate that the most renowned and advanced clinics are those which have attached to themselves competent laboratory assistants and have been in close touch with the laboratories of the medical sciences, or institutes of science allied to these, and whose directors are men well trained in laboratories. Professors in medical sciences should be men who know considerably more of the subject they teach than the clinically trained men in medical schools ever hope to know, on account of the little time the active clinical man can give to keeping pace with any medical science.

Special Eleventh Annual Summary of Fourth of July Injuries.—In a special article it is stated that the Journal made this year extra effort to secure complete and accurate data, and reports the smallest number of deaths from lockjaw and other causes since it began the collection of statistics. There has also been an astonishing reduction in the number of injuries. There are, however, still two many of these, and it feels that it is necessary that the campaign should be continued until the nation's disgrace shall be entirely removed.

MEDICAL RECORD.
August 30, 1913.

Further Experiences with Duodenal Ulcer.—Max Einhorn, having referred to a paper of his, published in 1909, in which he described six cases of this affection in which the thread test was the mainstay for diagnosis and cited the literature up to that time, states that it appeared of interest to him to broach the subject anew on the basis of his recent experiences. Most of his cases have been treated medically, and but a comparatively small number have been operated on. In order to show the value of diagnostic signs the material operated on (seventeen patients, whose histories are reported in the paper) is used as a guide. The seventeen cases are divided into six groups, as follows: 1. Duodenal ulcer with positive thread test confirmed as such by operation—seven cases. 2. Duodenal ulcer with positive thread test not confirmed by operation—two cases. 3. Duodenal ulcer found at operation with a negative thread test—one case. 4. Probable duodenal ulcer in which operation failed to find the seat of trouble—one case. 5. Gastric ulcer with positive thread test confirmed by operation giving clinically the symptom complex of duodenal ulcer—three cases. 6. Periodic recurrent pains in the upper abdomen with negative thread test confirmed by operation as to the absence of duodenal ulcer—three cases. The indications for surgical interference in duodenal ulcer are given as follows: 1. Perforation requires immediate operation. 2. Recurrent profuse hemorrhages endangering the life of the patient require a prophylactic interval operation. 3. Frequent small hemorrhages, not influenced by rational treatment and leading to an appreciable degree of constant anemia, demand operative intervention. 4. Cases with constant continuous superficial ulcerations, accompanied by intercurrent ischachymia, not yielding to treatment, should likewise be operated in. 5. Severe pains, not influenced to a considerable extent by a repeated course of rational medical treatment, constitute a strong indication for operative measures.

The Pathology of Simple and Exophthalmic Goitre.—Louis B. Wilson, after an examination of the thyroid glands removed from 1,208 patients in the Mayo clinic presenting symptoms which would ordinarily be diagnosed as exophthalmic goitre and, for purposes of control, 585 thyroids removed during 1912 from patients whose condition would ordinarily be diagnosed as simple goitre, arrives at the following conclusions: 1. A detailed pathological study of fixed tissue preparations of the thyroids removed from adults, and the finding thereof of marked primary parenchymatous hypertrophy and hyperplasia, permit the pathologist to diagnose exophthalmic goitre with about ninety-five per cent. of accuracy. At the same time, a consideration of the data observed during the examinations will permit him to estimate the stage of the disease in about eighty per cent. of the cases and the severity of the disease in about seventy-five per cent. of the cases. 2. A similar study of thyroids from adult patients, and the finding thereof of no marked hypertrophy, hyperplasia, or regeneration of parenchyma, will permit the pathologist to diagnose nontoxic goitre with about seventy-five per cent. of accuracy. 3. The most difficult cases to diagnose pathologically are those of the clinical toxic nonexophthalmic type. Our knowledge of these cases is still too incomplete to permit of conclusions concerning the details of their pathology. 4. On the whole, it would appear that the pathologist has quite as much data for the estimation of the clinical symptoms of exophthalmic goitre from the pathological data to be obtained from a study of the thyroid, as he has to estimate the clinical symptoms of Bright's disease from the pathological data to be obtained from the study of the kidney.

Results of Intravenous Injections of Extracts of Goitre on Blood Pressure in the Dog.—J. M. Blackford and A. H. Sanford find: 1. A powerful depressor substance exists in exophthalmic goitres. 2. A primary injection establishes tolerance to the action of further injection. 3. Atropine does not inhibit its action. 4. The substance does not behave physiologically like cholin. 5. The action is chiefly through peripheral dilatation aided by some diminution in cardiac output. 6. Irritability of the va-
gus is not increased. 7. The existence of a crossed tolerance between the depressor action of extracts of exophthalmic goitres, and of serum from patients with exophthalmic goitre, suggests that the two substances are the same.

Clinical Interpretation of Chronic Abdominal Enlargement in Children, with Special Reference to a New Differential Sign between Rachitis and Tuberculous Peritonitis.—Herman B. Sheffield, while stating that a positive tuberculin reaction is, of course, corroborative of the diagnosis of the latter, emphasizes the point that a negative result by no means proves the absence of tuberculosis. The physical sign to which he calls attention is the following: Whereas in rachitis the greatest prominence of the abdomen is manifested at the epigastrium, in tuberculosis the abdominal circumference is greatest at or below the umbilicus. This sign can be explained by the fact that in tuberculous peritonitis the inflammatory exudate accumulates at the bottom of the abdominal cavity. To make correct use of the sign it is necessary to exclude large dermoid cysts of the ovary and an overstretched bladder. Another possible source of error is congenital or acquired hypertrophy and dilatation of the colon (the so-called Hirschspring’s disease), but with the help of the x-ray the diagnosis can be readily made.

Congenital Stenosis of the Pylorus.—August Strauch gives a detailed report of a case of this condition, and states that, during his observation, at least, the case never seemed to him to present an indication for surgical interference, though several physicians urged an immediate operation as the only means of saving the patient’s life. The child recovered completely under expectant treatment, though, on account of the mother’s disregard of medical advice, this was conducted under very unfavorable conditions. The author quotes various authorities on the subject, and appears to agree with Heubner, who concludes that the great majority of cases offer, in spite of the hopeless aspect, a good prognosis, especially in private practice. As to operation, Heubner considers the moment for this to have arrived when the first symptoms of tetany make their appearance.

ANNALS OF OPHTHALMOLOGY.

July, 1913.

Color Adaptation.—F. W. Edridge-Green summarizes his paper thus: 1. In color adaptation the retinocerebral apparatus appears to become less and less sensitive to the color corresponding to the dominant wave length, and to set up a new system of differentiation. 2. When light of a composition differing from that of daylight is employed to illuminate objects, an immediate and unconscious estimation of the colors of these objects is made in relation to this light, the light employed being considered as white light. 3. No color is seen of which the physical basis is not present in the light employed. 4. When spectral regions are examined with a color adapted eye, that of the dominant wave length appears colorless, while those immediately on either side of it appear to be shifted higher and lower in the scale respectively. 5. There is immediate color adaptation after a longer stimulation with the adapting light. 6. Colors which correspond to the dominant wave length of an artificial light are with difficulty discriminated from white by this light. 7. Color adaptation may bring two colors below the threshold of discrimination, so that the two appear exactly alike, although by another kind of light a difference is plainly visible. 8. Color adaptation increases the perception of relative difference for colors other than the dominant. 9. The conscious judgment of this has very little effect in color adaptation. 10. Color adaptation greatly helps in the correct discrimination of colors and masks the effects of the very great physical differences which are found in different kinds of illumination. 11. Spectral yellow, after color adaptation to green, still appears yellow and not red. 12. Color adaptation appears to produce its effects by subtraction of the dominant color sensation, and not be directly increasing the complementary. Spectral blue does not appear brighter after color adaptation to yellow.

ANNALS OF SURGERY.

July, 1913.

An Analysis and Study of 724 Major Amputations.—W. L. Estes asserts that mediotarsal and tarsal amputations are preferred whenever practicable when amputation of the foot is required. It is especially necessary to obtain good, adequate flaps and cut the anterior tendons long enough to be secured by sutures to the posterior flap when forming the stump. Low down in the leg anteroposterior flaps are preferred, but not the Teale method or any extraordinarily long anterior flap method. In other parts of the leg lateral flaps seem best. At the knee joint a long anterior and a short posterior flap method is preferred. The patella may be removed or not, according to the conditions of the case. From the lower third of the thigh to the hip joint, anteroposterior flaps, with the anterior one longer, are usually employed. The writer always shapes the flaps from without inward, never by transfixion. The average time in the hospital of amputation cases ought to be about twenty-two days. The important factors in lowering the mortality of amputations for injuries are: 1. Saving of blood; 2, careful asepsis or antisepsis; 3, discriminating when to operate. The first two will no doubt appeal to every surgeon. The last one may be resolved practically into the determination of the blood pressure. Operate as soon as the blood pressure will permit. A systolic pressure below 80 should contraindicate operation.

Snapping Hip.—J. F. Binnie presents two cases of snapping hip. The first patient complained of: 1. A marked rubbing pain at the crest of right ilium when he carried a heavy weight. This had no relation to the occurrence of his second complaint. 2. When he jumped or carried a heavy weight there was an audible and palpable snapping at the right hip, which he attributed to the head of the femur becoming dislocated, and which he could produce voluntarily. At the operation it was found that there was a sausage shaped thickening of the fascia posterior to the wound and to the great trochanter (the fasciogluteal tract of Heuliy). A flap of the periosteum was raised, by a longitudinal incision.
from the femur at the lower part of the trochanter major and the posterior lip of the incised fascia lata was sutured to this and to the vastus externus muscle near its origin. The anterior lip of fascia was sutured to the posterior in such a manner as slightly to overlap the original line of suture. The skin wound was closed and the limb fixed in splints. The patient was seen a month after operation, when he was able to work. There was no recurrence of the snapping.

Hygroma Cysticum Colli.—Charles N. Dowd says that cystic hygromata of the neck have been described for many years and their existence is undoubtedly. The terms should be restricted to cysts lined with endothelium and having a marked power of growth. Such systic growths are uncommon. A careful search of the literature has so far revealed records of only ninety-one cases located distinctly in the neck, and thirty-five cases located principally in the axilla, but in part at least extending there from the neck. The writer records three cases of undoubted hygroma and a fourth case which is believed to have been a hygroma but in which inflammation had destroyed the finer structure of the cyst walls. The most satisfactory explanation of the existence of these hygromata is that embryonic sequestrations of lymphatic tissue existed, and that they had the power of persistent irregular growth. Excision is the best treatment. If this is impracticable partial excision is the next best.

INTERSTATE MEDICAL JOURNAL.

August, 1913.

Ulcerative Colitis.—From his studies A. Bessler concludes that there is a chronic form of dysentery due to the Bacillus coli communis, which is not uncommon in temperate climates; that the organisms exist in large numbers in the lower intestinal tract, mostly in the mucus; that they are capable of destruction of tissue locally, with the production of ulcers, and then living within the tissue of the gut wall in the bases of these; and that there is reason to believe that in this disease we are dealing with an organism of the colon group specialized in nature. The disease varies greatly in severity, but most patients go steadily downward from the first, lose much weight, seem unable to digest anything, and in a few weeks become wasted skeletons. The temperature is often raised two or three degrees, and its irregularity is suggestive of septic poisoning. The desire to go to stool is sudden and urgent, but defecation is not usually attended with tenesmus unless there is ulceration of the rectum. Not infrequently there are considerable abdominal pain and tenderness. Relapses are common in cases which do not prove fatal. When death occurs it is usually due to exhaustion, less frequently to perforation and general peritonitis, and occasionally to hemorrhage. The diagnosis should not be difficult, as the pelvic colon is always involved, and this can be directly examined with the sphygmoidoscope, which should, however, be used with much care. The paper deals also with anemic and bacillary dysentery and their treatment. In the treatment of the colon bacillus infections of a chronic nature rest is not so important as in these, although advisable. The diet should at first be of liquid character, and, when the diarrhea has subsided, semisolid, with scraped meat. The usual methods for the control of diarrhea are in order, and irrigation by enemas with the various solutions are called for. In four cases the author has employed autogenous coli vaccines, and in each instance a cure resulted in about three months. He gives in detail the report of one severe case in which appendicostomy was performed, followed by daily irrigations with saline solution. At present the appendix fistula is gradually closing, and the patient is entirely well.

Duodenal Ulcer, with Illustrative Cases.—L. H. Hempelmann, as the result of his observations, arrives at the following conclusions: 1. The "stomach trouble" lasting for years with hunger pains relieved by the ingestion of food or soda, with severe exacerbations followed by periods of almost complete freedom from discomfort, almost always indicates duodenal ulcer. 2. Duodenal ulcer is relatively not an infrequent disease, and in many cases its symptomatology is quite clear and its diagnosis easy. 3. Moynihan's dictum, that severe recurrent hyperchlorhydria is duodenal ulcer, is probably nearly true. 4. The danger of hemorrhage and of perforation, and the frequently resulting cicatricial stenosis after the ulcer has healed, make duodenal ulcer a serious disease, which should be treated vigorously—in recent cases by medical means and diet, and in chronic cases by surgical means.

The Iodine Treatment of Gonorrhea in the Female.—O. Hofmann, following the suggestion of Bovée, has in the past few months used the iodine treatment with excellent results, and thus describes the technique: Place the patient in the dorsal position, and, separating the labia with the thumb and index finger of the left hand, swab the parts thus exposed, and also the labia minora and inner surfaces of the labia majora, with a solution of 3.5 per cent. iodide crystals in ninety-five per cent. alcohol. Next search for the orifices of Skene's glands, and force into them a few drops of the solution by means of a hypodermic syringe to which is attached a long blunt needle; then search for and inject the external openings of the vulvovaginal glands. The author has not found it necessary to treat the urethra directly only exceptionally. The patient is now placed in Sims's position and, a Sims's speculum having been introduced, the vagina is swabbed dry with cotton and the presenting cervix (not the canal) painted thoroughly with the iodine solution by means of a cotton swab firmly fastened in a dressing forceps. After the anterior wall and both sides have been thoroughly painted, press the swab firmly up into the posterior cul-de-sac, partly withdraw the speculum, rotate it so that it will press against the anterior wall, and then reintroduce as far as possible, swab the posterior wall and remove the swab. Next introduce a very narrow strip of gauze as high up against the posterior wall as possible, remove the speculum, and allow the gauze to protrude beyond the introitus. The applications are repeated every third day in both acute and chronic cases, and two days after the third application smears are taken from all the structures involved. If the gonococci are still present the treatments are continued, and, in addition, vaccine treatment is begun.
The Quincy (Illinois) Typhoid Epidemic.—Jordan and Irons give a brief report of an epidemic of typhoid occurring in January, 1913. The investigation of the outbreak showed, as usual, that the infection had taken place as a result of the contamination of the drinking water by sewage. It was found that the rapid filter system as employed by the city was entirely inadequate to free the raw water from dangerous bacteria. To assist in the destruction of organisms calcium hypochlorite had been employed, and it apparently had been efficacious in some degree in preventing typhoid. The year 1912, during which the hypochlorite treatment was used for about nine months, had the lowest typhoid death rate recorded in Quincy. The amount of hypochlorite used in December, 1912, and the first few days of January, 1913, was much below the average for the preceding eight months. It was found that this period, during which an insufficient amount of hypochlorite was used, corresponds with the date when the maximum typhoid fever infection occurred and also with the date of an extensive outbreak of gastroenteritis. The resumption early in January of adequate hypochlorite treatment was followed by the immediate subsiding of the epidemic.

The Identity of Entamoeba Histolytica and Entamoeba Tetragena.—According to Craig a great deal of study during the past three years has been devoted to the parasitic ameba of man, especially to the species that have been described as causing dysentery, and considerable advance has been made in our knowledge of these organisms. Among the subjects investigated the possible identity of Entamoeba histolytica and Entamoeba tetragena, the species most often described as being associated with amebic dysentery, has attracted much attention, and the impression has been steadily gaining ground that these organisms, generally considered as being distinct species, are in reality identical. Craig comes to the conclusion that the typical histolytica nucleus occurs in the most acute cases of dysentery, while the tetragena type of nucleus is found in milder cases.

The Rôle of Staphylococcus in Gonorrhea.—Warden, in consequence of his investigations, tentatively concludes that many, if not all, of the Gram negative intracellular, biscuit or coffee bean shaped cocci, observed in the purulent discharge in acute gonorrhea, which are regarded as gonococci and which serve as criteria of diagnosis, are not gonococci, but belong to the staphylococcus group. He holds that true gonococci are demonstrable with difficulty or not at all, in smears of gonorrheal exudates or in preparations of tissues. The diagnosis of gonorrhea is to be made only by cultural methods.

Further Studies on the Effects of Desiccation on the Virus of Rabies, and the Use of this Material in Immunization.—Harris points out the great advantages of using desiccated virus in the immunization of those bitten by rabid dogs. It is safer than the ordinary method, in that the greater portion of the material injected is capable of immunizing without being infectious. It is economical both to the patient and to the laboratory, because it requires a much shorter time to administer a full treatment than most of the older methods. It is more convenient to prepare, as at one time enough material may be frozen, dried in vacuo, and sealed in glass tubes to last for from six to twelve months.

The Effect of Quinine on Dogs.—Moon conducted three experiments on dogs in order to determine whether the administration of quinine in rabid dogs would prove effective. The use of this drug was based on the possibility of rabies being due to a protozoan parasite. In each experiment the quinine was not given until symptoms of the disease became manifest. The untreated animals died, while the other three recovered. The author does not offer this method as a substitute for the Pasteur treatment; no other than the preventive method is to be considered during the incubation stage of the disease. But when active symptoms have developed, the Pasteur treatment is hopeless, while the treatment described may offer some hope if instituted without delay.

Pharmacological Action of Helenin.—P. D. Lamson presents a study of helenin, the active principle of Helenium autumnale, a well known American plant growing to a height of two or three feet, with large yellow flowers, and popularly known as the sneezeweed, swamp sunflower, yellow star, ox-eye, etc. Helenin is a neutral, crystalline substance, reducing alkaline copper mnnite solution on slight warming. It is not a glucoside, containing no carbohydrate group. It is a very active irritant to mucous membranes, causing sneezing and lacrimation when brought in contact with the nasal mucosa and conjunctiva, vomiting and diarrhea when ingested, and edema when subcutaneously injected. It is a direct paralyzant to the heart muscle, and acts severely on the respiration, the rate and force of which are increased, while the volume of expired air is diminished. The pure helenin, given to animals, produces the same symptoms as those formerly described in poisoning of cattle after ingestion of the entire plant. The giving of melted lard to poisoned cattle would appear rational from the results of the author’s experiment in which helenin was given internally to a dog. This plant is probably a cause of fall hay fever. As to the many medicinal uses of helenin mentioned in the literature, as a tonic, snuff, febrifuge, anthelmintic, diuretic, and as an antitoxin for “cold” and venereal diseases, its pharmacological properties certainly justify its use as an errhine. It could be employed as a stomachic in small doses. Its intense gastric irritant action would exclude its use as a vermifuge except in very dilute solutions. Its properties do not justify its use as an antipyretic, nor for any of the other purposes already mentioned.

Action of Diuretics in Uranium Nephritis.—W. De B. MacNider finds that in dogs in which acute nephritis has resulted from the subcutaneous administration of uranium nitrate, the changes in
the kidneys, as well as the glycosuria and polyuria, are more marked in adult than in young animals. When such nephritic animals are anesthetized by chloroform and alcohol, or morphine and ether, the severity of the nephritis is increased. Some animals after the anesthesia become anuric, and these fail to respond to diuretics, probably owing to a destruction of the renal epithelium. Others remain able to secrete urine and respond to diuretics; in these the renal epithelium is much less severely involved.

Influence of Atophan on Uric Acid Elimination.—Otto Folin and Henry Lyman found that phenyl quinoline carboxic acid (atophan) not only brings about an increased elimination of uric acid through the urine in gout, and a diminution of the uric acid in the blood, but also seems to diminish the nonprotein nitrogen and urea whenever these are present in the blood in unusual amounts. The drug acts, however, on the kidneys, and does not "mobilize" deposited urates.

OPHTHALMOLOGY.

Further Experiences with My Sclerotomia Cruciaita Multiplex (Grilliike Sclerotomy).—M. Wicherkiewicz devised a few years ago a new operation for certain forms of glaucoma, particularly glaucoma simplex and those in which other operations had produced no lasting effects. The operation is based on the theory that simple glaucoma depends on a rigidity of the sclera, which may also be thickened, that interferes with the intraocular change of fluid. He calls attention to the fact that intracocular tension and rigidity of the sclera do not always coincide, but may frequently show an opposite behavior. The rigidity of the sclera may appear intense, and the tonometer placed on the cornea may register no increase of tension; he has also seen the tonometer record a high pressure when the sclera was atrophic and soft. The technic of the operation is as follows: After instillation of cocaine a subconjunctival injection of a one per cent, solution of cocaine with epinephrin is made into the upper temporal region of the eyeball. While an assistant rotates the eyeball far downward with a sharp hook inserted above the cornea, a long meridional incision is made through the conjunctiva. The subconjunctival tissue is lifted up with two forceps, and incised, to lay bare a considerable area of the sclera, the bleeding being controlled by instillations of epinephrin. After the sclera is largely exposed, from four to six meridional incisions, ten to twelve millimetres long, are made in it with a Graefe knife, and then as many cross sections, as far back as possible. If the sclera is very thick some of the incisions are deepened, but only for from two to three millimetres, as far as to the choroid. After irrigation with saline, or boric acid, solution the wounds in the conjunctiva and Tenon's capsule are closed with sutures and a bandage applied for a day or two. Generally the intraocular tension is considerably diminished immediately after the operation, particularly if the eye is massaged, which always should be done before the dressing is applied. Later measurements of tension sometimes show that the tension rises at first, but it sinks after about two minutes of massage, and remains normal, with few exceptions, when the massage has been discontinued. In conclusion he says that he does not consider the operation to be a panacea for any form of glaucoma. All that he claims for it is that it is perhaps the only rational method against glaucoma simplex.

SURGERY, GYNECOLOGY, AND OBSTETRICS.

Ruptured Uterus.—C. H. Davis states that rupture of the uterus is probably a more frequent complication of pregnancy than is indicated by the statistics of the earlier writers. The difference between complete and incomplete rupture is one of degree. It is probable that most ruptures are at first incomplete. As complete rupture increases the shock and danger from all hemorrhage and sepsis, it is the more dangerous complication. The rupture involves the lower uterine segment, and the cervix in at least 53.8 per cent. of cases, the rent being more often on the left side and frequently involving the uterine artery. Certain ruptures may be prevented by close observation of the case during pregnancy, and by "good obstetrics." A considerable number of ruptures follow Cesarean section. A woman who has had a Cesarean section should be confined in a hospital in subsequent pregnancies, preferably by a section shortly before term, as we cannot know the condition of the scar area. The tamponade and binder are good temporary measures and may give good results in the incomplete cases where there is little hemorrhage, but in all classes of cases operative treatment gives better results than conservative methods, and should be employed whenever possible.

Retrograde Incarcerated Hernia: Hernia "En W."—L. Friedman says that the following symptoms and signs have been observed as being present in the few cases reported: 1. Large sized tumors in the scrotal region, sometimes asymmetrical, due to the distended separate loops; 2. colicky pain in the lower abdomen, on the side of the hernia; pain on pressure on the side of hernia, right above Poupart's ligament; 3. rigidity above Poupart's ligament on the side of the hernia; 4. local tenderness, due to the distended incarcerated loop; 5. presence of a sausage-like mass in the lower abdomen, on the side of the hernia; 6. perceptible asymmetry of the lower abdomen, the hernial side being higher; 7. dullness on percussion of the flanks, due to fluid, and a perceptible fluid wave; 8. Blumberg's sign of peritoneal irritation may be present; 9. greater abdominal than scrotal tenderness. After opening the hernia sac: 1. The presence of two or three separate loops of gut; 2. the escape of fluid, clear or bloody, from the abdominal cavity, after cutting the constricting ring. The time elapsed since incarceration has taken place will naturally vary the degree of the symptoms present. Because of the extreme rapidity of gangrene in the incarcerated loop, early operation is of great importance.

Three Finger Fluctuation.—W. Sampson Handley recommends that the tips of the two forefingers and of the middle finger of the left hand
are firmly planted upon the swelling, marking out an equilateral triangle of an area rather smaller than the limits of the swelling. The right forefinger is next sharply pressed into the swelling at right angles to its surface. Fluctuation is present only if the two fingers of the left hand move away from each other horizontally in the plane of the skin, at the moment when this is done. Any movement of the fingers in a vertical direction is to be ignored. This three finger or expansile method of testing for fluctuation effectually distinguishes real fluctuation from the pseudo-fluctuation of substances such as muscle and fat.

Method of Ventre-fixation.—D. Stetton performs a median laparotomy and ligates the round ligaments, about two inches from the uterus. They are divided proximal to the ligatures and freed from the broad ligaments up to the uterine cornua by a few snips of the scissors. The peritoneal edges of the incisions in the broad ligaments are united by a running catgut suture. Ligatures are now passed through the broad ligament between the tubes and ovaries, and the tubes are freed to their uterine attachment. The freed round ligaments and tubes are now brought through a stab wound in the fascia, muscle, and peritoneum on either side, three quarters of an inch away from the edge of the abdominal incision. They are drawn taut, and fixed to the fascia with a catgut suture. The peritoneum is closed with continuous catgut, one stitch passing through the fundus of the uterus, the surface of which has been seared. The muscle and fascial layers are closed in the usual manner with interrupted chromic gut sutures. The excess of tube and round ligament is removed and the tubes are ligated, the stumps being seared with a Paquillin cautery. Enough of the tubes and ligaments should be left so that they overlap in the median line. They are stitched to the fascia, and to the structures of the opposite side, with a few sutures of catgut. The skin wound is closed completely.

PROCEEDINGS OF SOCIETIES.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held May 19, 1913.

The President, Dr. REYNOLD WEBB WILCOX, in the Chair.

The Work of United States Army Surgeons in the Last Few Years.—The general topic of the evening was Tropical Diseases, and in a few introductory remarks the president, Dr. Wilcox, referred to the brilliant scientific achievements of our army surgeons in sanitation and the conquest of disease, saying that, not only had they made great scientific discoveries, but, by the practical application of their knowledge, they had accomplished results in Cuba and Porto Rico, the Philippines and Panama so remarkable as to win the admiration of the world.

The Sanitary Problems of the Philippines on American Occupancy.—Colonel L. Mervin Maus, Medical Corps, U. S. Army, read this paper, in which he showed the great progress made in the Philippines through the brains and work of American hygienists.

Observations on Beriberi in Japan and the Philippines.—Major Lewis G. Ness, Medical Corps, U. S. Army, in this paper, brought out the following points: 1. Recent investigation into the etiology of beriberi and observation of the disease among the native troops, and the natives of the Philippine Islands, and the numerous cases occurring in the Japanese army during the Russo-Japanese war, would indicate that beriberi was due more to the lack of nitrogenous food, and a diet largely composed of carbohydrates, than to a specific organism. At least, diet was an important predisposing factor in its causation. 2. While beriberi was apt to occur endemically and epidemically, it was extremely doubtful whether it was contagious, or could be transmitted from man to man. Hence, it should not be classed in the category of infectious or contagious diseases. If beriberi were caused by a specific organism, this certainly could not have any pathogenic action upon healthy and well nourished individuals. It was possible that individuals who subsisted mostly on a diet largely nitrogenous had a natural immunity against the specific organism of beriberi, and that this organism could act only on individuals who had a lowered resistance from the use of food consisting largely of carbohydrates, and in the presence of certain meteorological and other conditions. 3. The results and findings of the United States army board of medical officers for the study of tropical diseases as they existed in the Philippine Islands, in regard to the influence of rice diet and inanition in the production of multiple neuritis in fowls, and the bearing thereof on the etiology of beriberi, was a further proof that the lack of nitrogenous food and the excess of carbohydrates constituted an important factor in its etiology, if not the specific cause, of beriberi. As the result of a series of experiments on chickens, they were able to produce in the birds a multiple neuritis similar to that occurring in human beings suffering from beriberi by feeding them on polished rice; and, on the other hand, were able to cure them by feeding them on the polishings of rice, or the pericarp of the rice. Moreover, fowls fed on undermilled rice (that with some of the pericarp left on) did not become affected with a neuritis. While chickens and other fowls were very prone to be attacked with a general neuritis under certain conditions, it was believed that these experiments pointed strongly toward rice as constituting an important factor in the causation of beriberi. By way of confirmation of these experiments, the rice in the ration of the native scouts in the Philippine Islands (of which it largely consisted) was changed to the native rice, which was undermilled; and the result was the complete disappearance of beriberi among them. 4. Beriberi had always been classed as an unpreventable disease, and was so considered by the Japanese, who reported over 97,000 cases during the Russo-Japanese war. It should now be classed as a preventable disease, and there was no excuse for its occurrence among
troops, any more than there was for that of small-pox, typhoid fever, dysentery, cholera, and similar diseases which in the past had at times almost rendered armies ineffective and had often been a potent factor in deciding results between contending forces. As a matter of fact, Major Ness said, there was reason to believe that the wide prevalence of beriberi in the Japanese army had had a very considerable influence in bringing about the termination of the late war. In regard to the very considerable immunity from typhoid fever among the Japanese troops, about which so much had been said, this was practically due to the simple facts that the Japanese were extremely fond of tea (the water used thus being boiled) and of cooked foods; and the same thing was true of the Russians. On the other hand, our soldiers in the Spanish-American War did not like tea and drank much water, while they preferred raw to cooked foods. There was, however, some typhoid fever among the Japanese in the war with Russia; the number of cases, according to their own reports, amounting to more than 9,000, while there were over 4,000 deaths, a mortality of nearly fifty per cent. Among the Russians there were a little over 10,000 cases, but there were only about 1,000 deaths, a mortality of one fourth that among the Japanese.

Dysentery in the Tropics.—This paper by Major Eugene R. Whitmore, Medical Corps, U. S. Army, was published in our Journal for August 9, 1913, p. 257.

Dr. Nathan S. Jarvis referred to the views on the tolerance of the white man in the tropics expressed by the noted sociologist Benjamin Kidd in his book entitled, The Control of the Tropics, which was published no longer ago than 1898. It was then the practice in the British army to allow officers who had served one year on the west coast of Africa a year's leave, and this was also the rule in regard to those serving in India. This was on account of the conditions, so unfavorable to the white race, prevailing in those tropical regions. Now, however, it was possible for the white man to live indefinitely and comfortably in the tropics. This was very largely owing to the splendid work accomplished by the medical officers of our army, and the praise which was their due should be unstinted. At the same time, it should not be forgotten that in recent years the army surgeons had had the warm cooperation of the line officers, and such results could not have been attained without this. Formerly the case was different, and he could well remember that twenty years ago, when he himself was in the army medical corps, it was almost impossible to get the line officer to take any interest whatever in sanitary matters. Panama might be cited as an instance of the marvelous change which had been effected. In regard to the freedom from disease of the Japanese in the late war with Russia, this had undoubtedly been exaggerated, but he would say, in justice to some of those who had extolled the sanitary triumphs of the Japanese, that they had been deceived by the latter; for the reports which were furnished to them were both very incomplete and very erroneous. We should not lose sight of the fact, however, that the discipline in the Japanese army was really wonderful. In the case of volunteers, such as our army was largely composed of in the Spanish-American War, it took a year or two before the men could be depended upon to obey orders in a reasonably satisfactory manner. The results accomplished by the Japanese had, as he had said, been exaggerated; but they did get results, and this was due to their efficient discipline.

Special Meeting, Held in the Borough of Richmond, June 2, 1913.

Dr. William Bryan in the Chair.

An Unusual Case—An Entire Tendon of the Flexor Profundus Digitorum Torn from Its Sheath.—Dr. F. T. Donovan presented the specimen from this case. The patient was a boy who worked in a paint factory, and the distal phalanx and head of the next phalanx of one of his fingers were taken off by a wooden paddle in a paint mixing apparatus. With these came away the whole flexor tendon of the phalanges, which was severed from its attachment in the upper forearm, and this was shown by Doctor Donovan. The patient suffered at first from shock, and it was feared that infection might occur later, but, fortunately, a good recovery was made without any drawbacks.

Report on the Recent International Congress of Physical Education in Paris.—Dr. M. S. Gabriel said that the International Congress of Physical Education and Sport, which lasted four days, was inaugurated on March 17, 1913, in the presence of the President of the French Republic and delegates from twenty-six nations. The work of the congress was divided into two parts, reading of papers and demonstrations. There was also a large exhibition of drawings, paintings, statuary and apparatus to illustrate gymnastics, aeronautics, mountain climbing, touring, yachting, and rowing. The demonstrations were followed with the keenest interest. Several countries had sent representatives to render the demonstrations of various gymnastic methods complete. France had twelve groups. civil, military, and marine. There were four groups from Belgium, one masculine and one feminine group from Denmark; one group from Italy, one from Sweden, and one feminine group from Germany. The English method was demonstrated by a group of thirty young women. The last gathering of the congress was devoted to a banquet, followed by a musical entertainment, and as Dr. Gabriel was the only American member present, the pleasant duty of making a farewell speech on behalf of America devolved upon him.

The Treatment of Arteriosclerosis.—Dr. Louis F. Bisnopr, in this paper, said that the reason so little advance had been made in the knowledge of the treatment of this disease was that it labored under a misnomer, and attention had been directed to the structural change in one set of organs, the blood-vessels; while, as a matter of fact, the tissues of the whole body were equally the seat of the disease. The clinical condition known as arteriosclerosis no
more consisted essentially of sclerosis of the arteries than typhoid fever consisted of ulceration of the intestine. Arteriosclerosis was a disorder affecting the cells of the whole body, including the blood vessels, in such a manner that after a time circulatory difficulties arose, and the heart, blood vessels, and kidneys became conspicuously involved. This might be due to other causes, but it seemed to him that in the vast majority of instances it could be traced to the effect of substances which were ordinarily derived from proteins taken into the body as food. It was not the effect of proteins on the individual, but the reaction of the individual to the proteins. The vegetable proteins apparently caused the least harm. Arteriosclerosis was liable to begin when, through some accident of food poisoning, severe illness, nervous shock, or some unknown incident, the cells of the body became sensitive to particular proteins found in customary food: and later there was a continuous subsymptomatic anaphylaxis, leading to irritation and finally to changes in the tissues—perhaps to replacement of some of the cells by connective tissue. This took place in all parts of the body. The impairment of the organs led to failure of internal secretions and of general metabolism, and the individual who started with a sensitivity to a single protein would, after perhaps twenty-five years, be found presenting the picture of the terminal stages of so-called Bright's disease. If this was a true statement of the conditions found the treatment of arteriosclerosis must consist in the discovery and removal from the dietary of such protein, or proteins, as were inimical to the individual person, and, as the absorption of protein was profoundly affected by the condition of the intestinal canal, much attention was justifiable to intestinal putrefaction and auto-intoxication. These considerations had led him to the development of a system of diet which he had termed the "few protein diet." The treatment of arteriosclerosis consisted in a modification of such a plan as one would use in acute food poisoning. In the presence of well developed arteriosclerosis, with subsymptomatic continuous anaphylaxis, an ounce of castor oil was ordered every forty-eight hours for three doses. Then, after a week, another dose was given, and after that, a dose at least once a month as long as the patient was under observation. Out of the diet were taken all eggs, fish, meat, and poultry, and all soups except vegetable soups made without stock. Cheese was allowed, as furnishing protein in a safe form, and, later, chicken, if experimentally it was found that as a result the blood pressure was not increased. Iodine, he believed, did as much good in small doses as in larger ones. As to the reduction of blood pressure by drugs in this disease, nitroglycerin was the great symptomatic remedy for all emergencies arising in its course, whether these were attacks of dyspnea, pain, vertigo, or even edema of the lungs. Out of door exercise was essential to the welfare of the sufferer from this condition. For the cure of arteriosclerosis the underlying secondary causes had to be removed. Among these mental stress was the most important, and the development of a sound philosophy of life was necessary to go with the castor oil, the low protein diet, and the out of door life.

Dr. I. L. Nascher said that in dealing with arteriosclerosis, not the complication of pathological conditions, but the disease of the vessels alone, we failed to consider that there were many varieties of arteriosclerosis. It was only in the later stages that they assumed a common type, an arteriophibrosis and, later, calcification. The ordinary pathological form of arteriosclerosis began as an endarteritis, due to some irritating ingredient or constituent of the blood. This form of arteriosclerosis was amenable to treatment. There was a physiological arteriosclerosis which began with a loss of tonicity in the muscular fibres of the media, and this was the basis of Thomas's theory of senescence. No drug treatment was of benefit in this form of arteriosclerosis, but it was possible that the tonicity of the muscular fibres could be partially and temporarily restored by the high frequency current. There were probably two or more varieties of arteriosclerosis which began in insufficient nutrition. The usual treatment of arteriosclerosis with potassium iodide was of service only in a few of the pathological varieties. The potassium base diminished the viscosity of the blood, and permitted a freer circulation; but after the stage of fibrosis was reached it was useless, except that the potassium base diminished the viscosity of the blood. The low protein diet struck at the etiological factor of arteriosclerosis caused by excessive proteid intake; but where an arteriosclerosis occurred in the course of syphilis, nephritis, gout, or diabetes, the success of the treatment depended upon the results obtained in the primary disease.

Dr. J. Milton Marbott asked Doctor Bishop if he considered the glycerophosphates of value in arteriosclerosis.

Doctor Bishop said that glycerophosphates were useful as a general tonic, but had no effect on the condition present. In our chronic cases of cardiovascular disease we all gave iodine, under the impression that it had a systemic effect, and there was a strong tendency to the opinion that the good it produced was due to its activating the ductless glands, and more particularly the thyroid. In reply to a question by Dr. Edward Wallace Lee as to the action of nitroglycerin, Doctor Bishop said that, as he had remarked in the paper, in cardiovascular cases with high blood pressure it was extremely useful, but purely as a symptomatic remedy. In this class of cases most of the distressing, and some of the dangerous, symptoms were due to local spasm in some part of the vascular system—there was a condition of overtone in some particular spot. In all such instances nitroglycerin, by its vasodilating action, relieved the spasm, and thus the distressing symptoms. He was therefore accustomed to direct his patients of this kind always to carry nitroglycerin tablets with them, so that they would be prepared for any sudden emergency that might arise.

Longevity and Rejuvenescence.—Doctor Nascher read a paper on this subject, which was published in this Journal for July 12, 1913, p. 61. Doctor Bishop said that one of the most interesting things to be noted about our modern life was the disappearance of old ladies and old gentlemen from society. The fact was that most old people of the present day had already adopted Doctor Nascher's
theory. Thus, his own grandmother, who was now eighty-four years old, considered herself as active as those about her, and insisted on going with the family to all sorts of entertainments—even to dancing parties, although she herself did not dance. In our time married couples did not grow old together in the way that was formerly the case. The cosmetic part of the treatment, at all events, he thought was pretty well covered.

Doctor Mabbot said that recently he had had occasion to give advice to a gentleman of great culture and refinement, a widower over fifty, who was attached to and desired to marry a young woman of twenty-five. He had expressed his hearty approval of such a marriage, and the gentleman felt very grateful to him. Yet when afterward Dr. Mabbot had mentioned to various friends, both lay and professional, the advice he had given, they all disagreed with him. If a young woman marrying an elderly man did not expect too much sensual gratification, she could be a very great help to such a husband, and add no little to his comfort in his declining years.

Doctor Lee said that, other things being equal, the matter of environment had a most important influence on whether individuals kept young, or the reverse. Thus, the inmates of old peoples' homes, where they were isolated with those of their own time of life and had little to vary the monotony of their existence, were apt to deteriorate rapidly. The companionship of young people had a marked rejuvenating effect, and there was nothing that would tend so much to keep an old woman young as the care of a young grandchild. With grandchildren, and perhaps great-grandchildren, about her, an old lady would almost invariably feel young and act young; and the whole tendency of such environment would be to keep her in good physical condition. The speaker then said that he heartily approved of the stand that Doctor Mabbot had taken in regard to a young marriage, and that, in general, society criticized such marriages too severely.

Doctor Gabriel said that as to marrying a very young wife, it was recorded in the Bible that when King David was well stricken in years his servants procured the most attractive young woman that could be found "to lie in his bosom." Association of old people with the young was without doubt beneficial to the former, but might prove detrimental to the latter. Thus, he had once had under his care an anemic girl, eight years old, who did not improve, although various kinds of treatment were employed. Eventually he found that the child slept regularly in bed with her grandmother. This was of great benefit to the old lady, but it was at the expense of her granddaughter's vitality; and as soon as this practice was discontinued the girl began to improve rapidly. The occasional intercourse of an old husband and a young wife was no doubt of benefit to the man, but unrestricted intercourse would inevitably prove fatal to him. In this matter of longevity it was necessary to consider all the various elements affecting it. These differed with different individuals, and in each individual instance the special circumstances of the case had to be studied.

The chairman, Doctor Bryan, said it seemed evident to him that what we had to do to live long was to keep the system clear of "clinkers." The mischief working proteins should all be burned up, and for this, sufficient exercise, of whatever kind seemed most suitable, was essential. It was necessary that plenty of oxygen should be continuously taken into the body, and to this end all the improvements in our modern mode of life tended—the sleeping with open windows or in the open air, the outdoor life, with its varied exercise, etc. By whatever means, oxygen must be gotten into the system.
when pneumonia threatens to deviate from its normal course, and when 'nervous' (e., typhoid), symptoms appear—full, slender persons, rather inclined to stoop and be hollow chested, if you please, of the tuberculous habit. Both young men and women who have grown too rapidly, who have a delicate skin, and long, silky lashes; the mental development is excellent, yet they have no the physique to support this keenness of mind. Particularly is it indicated if they have an hereditary tendency to consumption, or have had bone disease in early childhood.

On the other hand, Potter or Wood, for instance, found out that in the phosphorus type, the consumption may be expected to return with a vengeance.

It is interesting, however, to note that Hare’s *Materia Medica*, fourteenth edition, says: “Phosphorus attacks the peristome, and pyogenic organisms then attack the bone. Sometimes the tubercle bacillus causes the necrosis. And as we have learned that the phosphorus actions are influenced by the phlogistic conditions in the blood, we would expect a tuberculous necrosis of the jaw in a phosphorus typed youth, employed in a match factory and living in a tenement cell."

And there is something more striking: That these provings and observations on the action of phosphorus pointed the way to its use as a curative measure in cases of the very same nature as Doctor Lemon’s, long, long before any such clinical tests as his, but furnishes another evidence of the correctness of the provings and applications gained by provings.

While the doctor conjectures as to the precise action of phosphorus, the solution of his puzzle almost slaps his face in the same paragraph, when he opines: “That the whole bodily condition shows renewed vigor under phosphorus in lung conditions, and that probably the patient lacked phosphorus.”

It never occurred to Doctor Lemon that phosphorus might serve as an antigen to some chest patients. Cohnheim, however, have long known that drugs have a synergistic action with certain vitamins, and that phosphorus may just as well stimulate antibody formation when the picture calls for phosphorus as a vaccine could help win the fight for the opsonin starving individual. So, the probability was overwhelming.

Drugs are more delicate and precise weapons than Doctor Lemon is accustomed to handle when administered in his dose to his patients; and when one deals in drugs as antigens, even though he but stumble blindly upon the indication, he must have a power of observation equal to the recognition of the aggravation or negative phase, similar to that of a Wright or Douglass, and scientifically reduce or regulate his dose; else, with such deep acting drugs as phosphorus he will duplicate the early experiences with tuberculin, and hasten many cases to a finish by aggravation.

Surely, Doctor Lemon’s paper is worthy of more thought than anything I have seen written on drugs in most journals. I fear many to think who before have never known phosphorus in this light.

Now, a problem and an answer! Acute and chronic bronchitis, pneumonia, tuberculosis indulge the use of phosphorus, according to Doctor Lemon.

How long before phosphorus will be forgotten on these indications? Already there are more drugs, prescrip- tions, and combinations, than you dare print, for these conditions. I agree; but I say, inasmuch as it is a great opportunity, and if we knew no more about when to give phosphorus than Doctor Lemon tells us, therapeutic oblivion awaits phosphorus.

A rhododendron culture, a drop of blood, and the microscope will tell you when to give 500 million dead typhoid bacilli, but it is more of a job to know when to give phosphorus. General and routine prescribing is always poor; giving this for that, because so and so said so, is ground sufficient for old wives and fisherwomen, but not for scientists. The cut, cut never was made with a different knife. Individualization is the keynote, and when the phosphorus picture fits the pneumonia frame the opsonins do the rest.

Very truly yours,

John H. Besson, M.D.

*Book Reviews.*

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

The large number of beautiful colored plates portraying eighty-six conditions of the fundus, give this book the appearance of an atlas, but, after an examination, the reader appreciates why the author has avoided the phrases, "diagnosis..." and chose the words "ophthalmoscopic diagnosis" to indicate its real purpose, which is to be a systematic guide to diagnosis of lesions in the fundus of the eye, with illustrations to serve simply as aids in the carrying out of the purpose, and it would seem that the book was designed to be of unusual value to practitioners who are not thoroughly conversant with ophthalmology; the text is clear, the illustrations life like, just the help needed in the study of ophthalmology. The book is a treasure, of much value to him in the excellent group of symptoms. He is an unusually fine diagnostician who can find it useless until him. As the author says, the technic of using an ophthalmoscope cannot be taught by a book, but the few suggestions that the minds may be of aid to the unex- perienced amount to a very clear and definite description of how to use the instrument, and how to overcome the difficulties that form stumbling blocks in the way of a beginner. It is plain that he has had much experience in teaching this subject. Then comes a description of the normal papilla and fundus, illustrated with schematic drawings to make the text clear, followed by large plates showing three different types of the normal fundus. The differential diagnosis of the white and yellow crescents to be seen about the papilla is then given and illustrated by several more colored plates, then that of the various forms of atrophy of the optic nerve, optic neuritis, choked disk, and retrobulbar neuritis. Then the vessels of the retina are studied, then the retina itself, with the hemorrhages, white spots, and diffuse opacities to be seen therein, and finally the diseases of the choroid. Each of these subjects is first dealt with in clear, concise language, and then illustrated by plates, to each of which is attached a brief, but sufficient description. The book is well bound and forms not only a useful, but an ornamental addition to the library.

A glance at the table of contents indicates the wide field into which the author attempts to delve. They start with the books of life and hit from the anatomy and physiology of the male generative organs to venereal diseases; to hermia; to self-abuse; to constipation; to happy marriages; to the development of life; to her to defer old age; and finally, appropriate, and end their diatribe on the secret of success. (We have here and there omitted the names of some of the chapters.) The book might appropriately be termed "Heal Thyself," as it covers all sorts of treatments and even goes so far as to suggest different methods for various ailments. They tell the patient (page 45) how to use the three glass test in examining for gonorrhea. The authors are not always accurate in their
statements; in discussing cystitis they say (page 38) "a majority of cases are due to gonorrhea." Much of the advice on sex questions is good.

**Geschichte der Ohrenheilkunde.** Von Dr. ADAM POLITZER, em. o. 6. Professor der Ohrenheilkunde an der Wiener Universität. Zwei Bände von 1880-1911. Unter Mitwirkung bewährter Fachkräfte. Mit 29 Bildnissen auf 29 Tafeln. Stuttgart: Ferdinand Enke, 1913. Pp. xxvi-684. Volume II of Politzer's *History of Otology* gives a complete account of the advances in knowledge made during the period covered by his work (1880-1911). Individual chapters are written by men of such standing as Alexander, Bárány, etc., mainly of the Vienna faculty, and the entire field of otology is covered. Following each chapter is an exhaustive bibliography of the subject just treated. The book is in two parts, the first being the historical aspect (pp. 1-215), while the second gives short accounts of the advances made in the countries of the scientific world, with mention of clinics and societies, and short biographies of the otologists in the different cities of the several countries. This aspect has been cared for by Dr. J. M. Hunt (for England), Dr. C. Chauveau (for France), Dr. L. Stern (for Germany), and by Dr. Clarence J. Blake (for the United States), to mention only a few of the collaborators. The book measures up to the standard that one would expect from a volume bearing Politzer's name.

PREOPERATIVE CAUTION TO AVOID POSTOPERATIVE CALAMITIES.*

By H. Augustus Wilson, M.D.,
Professor of Orthopedic Surgery, Jefferson Medical College.

The orthopedic surgeon is frequently the court of last resort for patients who have been subjected to various exploratory and other operations, and whose conditions have not been materially benefited thereby; especially when recurrence has taken place or entirely new features have ensued.

It seems desirable that every medical society should discuss the various phases and the many problems that arise in connection with the surgical treatment of diseases and abnormalities. Hence, it is fitting that the annual address before this learned medical society should deal with the necessity for preoperative care in diagnosis and caution with a view to avoiding postoperative calamities.

The past thirty years have seen wonderful progress, particularly in the line of new operative procedures, improved technic, and operating room facilities, the perfection of the relation of laboratories, and the special training of operators. These great improvements have resulted in increased demands upon the operators in the special lines of their work; but the brilliant results that have been achieved by many skillful operating surgeons appear to be leading them to perform exploratory incisions much more frequently than seems warranted, in order to avoid the laborious requirements of preoperative diagnosis. For instance, in a number of cases that I have known, had as much diagnostic care been exercised early in the course of the treatment as was finally displayed, the patients would not have been subjected to three or four unnecessary exploratory incisions before the true nature of their maladies was disclosed.

As an illustration of the dangers of presenting inaccurate preliminary reports and of making the results appear favorable, I refer to the report of a hospital that made the very truthful statement that during the preceding year not a single death had occurred in the hospital, a most enviable mortality record that could not be surpassed. The practice prevailed at this institution of removing all very seriously ill patients from the hospital to tents in the adjoining grounds. It is therefore easily understood that when death occurred it always took place outside of the hospital.

Accuracy and truthfulness are essential parts of statistical and individual reports of operations, but often too little time has elapsed, at the time of the report, to determine the end results. It is the experience of everyone who endeavors to hunt up a series of patients after several years, that from the changes of address and other reasons, subsequent details become impossible. These patients often become the subjects of reports by others than the surgeons who first operated upon them, and therefore a different aspect is presented.

A general surgeon of extensive experience recently told me that statistics gathered by him from a very large number of surgeons proved that twenty per cent. of all the cases operated in for appendicitis were no better after the procedure, and that thirty per cent. were distinctly worse; these figures being largely due, in his opinion, to errors in diagnosis. This statement, coming from such an authority, demonstrates that there is entirely too much heedless surgery.

Dr. Joseph M. Spellissy, in his annual address before the Philadelphia Academy of Surgery, reported one hundred and ninety-four cases of lesions diagnosed as appendicitis, covering twenty varieties of structure and embracing sixty-eight species of lesion, not one of which proved to be of appendicular origin. His conclusion follows: "A diagnosis in cases with symptoms pointing to the right iliac fossa should not be made without a routine, conscientious examination for, and exclusion of, the various troubles that may exhibit misleading symptoms and signs."

A very large number of persons carrying scars of appendectomy and other abdominal procedures are sent to the orthopedic surgeon for the relief of what proves to be tuberculosis of the spine. As an illustration I may mention a case in which the patient was operated upon three times within a period of two years, without benefit. The first operation was an appendectomy which revealed a normal appendix; the second, a draining of the gallbladder, nothing abnormal being found; and the third, an operation for enteroptosis. It was during the last procedure that a hitherto unsuspected psosas abscess was discovered. Had sufficient care in preoperative diagnosis been exercised the existence of this condition would doubtless have become known much sooner; and the patient would have been spared a long and tedious illness due to the tuberculous condition of the spine, ultimately resulting in death.

When such lesions are diagnosed early
enough, the proper treatment is frequently conservative, rather than operative. The almost invariably unsatisfactory result of operations on tuberculous joints has led most surgeons to avoid surgical interference, except when the recuperative powers of the patient appear to be equal to meeting the strain, and when improved function is sought. In my own experience, when I have postponed operating until I could build up the general health of the patient, I have often found that, with the improvement in the patient's physical condition, the necessity for radical measures has disappeared.

In considering postoperative calamities, I do not purpose dwelling upon the recurrences and fatalities in such conditions as cancer, due to delay in operating, or upon the necessarily fatal termination of many cases of injuries. I shall merely consider a few postoperative conditions, such as thrombophlebitis, nonunion after fracture, enteroposis, and persistent postoperative backache, in order to give emphasis to the statement that there are many factors that make the final outcome of a surgical operation uncertain.

Many writers have ascribed thrombophlebitis to infection, but its occurrence takes place where there is no evidence of sepsis. It often strikes like a summer storm out of a clear sky. It comes, when least expected, during convalescence from typhoid fever, after low forms of fat necrosis, and after severe infection in septic operations, and in septic cases prior to operation. It occurs even in simple exploratory cases that heal healthfully; and it attacks the patients of the most skillful, as well as those of the inexperienced operators. When once it has occurred, its further progress cannot be arrested, and its results cannot be overcome. If the patient survives, she must carry through life a swollen leg, and must suffer almost unendurable pain, the only relief being obtained from elastic compressure or disuse.

The routine method of operating upon simple fractures has been criticized by a number of authors. Dr. John H. Gibbon says that our aim should be to overcome the indications for open treatment by a perfection of our mechanical measures, and he further states: "One of the most valuable lessons which experience teaches is the estimation of risks and the value of precaution. It is the tyro whose boldness causes him to operate where an experienced surgeon recognizes danger, and it is the tyro who considers the refinements of an aseptic technic unnecessary or even looks upon them as fads. It is this type of surgeon who will operate on a fracture without having exhausted the less dangerous nonoperative means of reduction, and one reason why he does so is because he sees many worse cases operated in successfully by others. It may be said that this applies to the whole field of surgery, and so it does, but I hold that it applies particularly to the open treatment of fractures, where success depends so largely on the operator's mechanical skill and his practice of an aseptic technic."

Dr. John B. Roberts, in his paper on Operative Fixation as a Cause of Delay in Union of Fractures, cautions against the enthusiastic adoption of plates to maintain coaptation of fragments after difficult reductions. He considers the operative treatment particularly dangerous when adopted by novices in aseptic surgery, or where complete aseptic surroundings cannot be secured. Turck states that cases of primarily clean, closed fractures, often become converted into infected compound fractures by elective operation. He seems to think that the brilliant results obtained by some capable surgeons, through the use of clamps, Lane plates, medullary plugs, bone grafts, nails, wiring, staples, etc., have induced many less competent operators to undertake such measures, with unfortunate results.

Enteroposis presents another fertile field for postoperative calamities. Dr. Joel E. Goldthwait thinks that visceroposis is invariably associated with disturbance of poise, which must result in weakness of the muscles and strain of the joints; and that many of the chronic joint diseases are probably due to the disturbed physiology resulting from the malposition of the visceras, as well as probably to the absorption of poisons from the gastrointestinal tract.

Lund's instructive analysis, The Surgeon and the Posterior Problem (Medical and Surgical Reports of the Boston City Hospital, 1913), concludes: "In interpreting our end results, however, we must be particularly careful; cures will be rare. Even relief is a good deal. It is not an uncommon belief among surgeons that a careful review of the large number of cases reported by those who have operated freely in this field would show a large proportion of real failures from a therapeutic point of view. For this reason, conservatism and condon in reporting results are to be desired as well as optimism and courage in proceeding with this work."

The vast number of cases of persistent backache following operative procedure demands careful study and analysis, with a view to discovering its cause, as well as applying therapeutic measures for its relief. It has been demonstrated that the strained position on the operating table plays an important part in the production of this distressing postoperative condition.

From the facts herein stated, we may conclude that it is time to realize the dangers and uncertainties of the immediate and remote results of operations. Evidence is accumulating that operations are not always approached with careful preliminary study. The reason for this is that many surgeons belong to one of the two classes mentioned by Lund: "Those who, for the sake of increasing their income, are trying to learn surgery by practising on their private patient; and recent graduates of hospitals who assume that a superficial knowledge of technic renders them capable of coping with the problem of major surgery."

Whenever a surgeon describes a new operation that he has devised and successfully employed, he should lay emphasis on the fact that in order to avoid postoperative calamities no one should attempt to follow in his footsteps without the careful preparation that he has himself undergone.

That the necessity for elevating the standard of the requirements for practising surgery is becoming generally recognized, is shown by the fact that
there was organized on May 5, 1913, a society called the American College of Surgeons, whose object is to grant fellowships to those worthy of membership in the organization, and to formulate a plan of indicating to the public and the profession that the surgeon possessing such a fellowship is especially qualified to practise surgery as a specialty. While the formation of such a society gives promise of better conditions in the future, it must be remembered that even a beginner—not yet eligible to bear the awe-inspiring title, F. C. S. —may be a surgeon who gives to each case the elaborate preparation and careful analysis that will tend to ward off postoperative calamities.

As a matter of fact, the whole responsibility for careful preoperative diagnosis should not be thrown upon the surgeon. The internist should assume his proper place before and after operation. He should take part in the preparation of the patient, and in determining his ability to withstand the shock of the operative procedure; he should occupy a prominent position in judging of the diagnostic significance of the various laboratory reports; and he should be in close association with the surgeon after the operation. The prevailing custom in the better hospitals of having numerous consultations of surgeons with internists and specialists, together with elaborate laboratory studies, must inevitably result in safeguarding the best interests of the patients. Dr. George W. Guthrie is my authority for the statement that seventy-five per cent. of the patients that formerly went to the Mayo brothers, expecting to be operated upon, were sent away without operation. This is because these eminent surgeons often find, by means of an elaborate system of preliminary study, at the hands of numerous skilled investigators, that there are often better ways of curing the patient than by operation. The physician should not be too hasty in subjecting a patient to the surgical procedure and yet should discriminate in the avoidance of fatal postponement. When an operation is finally decided upon he should take pains to assure himself of the ability of the surgeon whom he recommends; because, when he suggests and operates with a surgeon he thereby tacitly assumes proportionate responsibility for the results.

1611 Spruce Street.

THE POSITION OF THE STOMACH IN CHILDREN IN RELATION TO POSTURE.*

An Analytical Study.

By James Warren Sever, M. D.,
Boston,
Junior Assistant Surgeon to the Children's Hospital, Boston; Surgeon to the House of the Good Samaritan, etc.

From the Orthopedic Department of the Children's Hospital, Boston.

This paper is the result of an effort on my part to determine the location of the stomach in relation to posture. Various other factors were also studied, of which I will speak. The work done has covered a period of over a year, and the conclusions are drawn from a careful study, by means of the x-ray and physical examination, of over eighty children. A criticism which may be made is that the data have been gathered from the so-called hospital class, which is supposed to be represented by individuals rather below par than above it, and also that these children would not have come to the hospital were it not supposed that they had something rather definite the matter with them. This criticism, however, is not well founded, for it can be stated that many of the children examined during this investigation did not represent abnor- mal or unusual types of the so-called normal child. The children examined came to the clinic in the majority of the cases because they were supposed to have round shoulders or prominent scapulae. The subject is one which cannot be presented adequately here by mere statistics, so that I shall offer a general statement of the conclusions arrived at through a study of these data. In a study of the literature on the subject we find much that will have to be discounted if not altogether discarded in the future as we become more cognizant of the subject, and I believe that so far we have been led to lay undue stress on the condition of so-called visceral ptosis, congenital or otherwise, in children. Now what is the normal position of a child's stomach? I cannot find that this question has ever been accurately determined.

Holt (1) states that if the lower border of the stomach comes nearly to the umbilicus the stomach is dilated, and if it is below the umbilicus it is much dilated. Practically all textbooks and monographs on the subject speak of the normal position of the stomach as being well above the umbilicus, the lower border being in the region of the second lumbar vertebra. Butler (2) found in an examination of 155 children that forty per cent. had the lower border of the stomach when distended by gas within a half an inch of the umbilicus. In several older children who had bismuth examinations of their stomachs, the picture showed the lower border of the organ below the umbilicus, but these cases showed also the typical enteroptotic habit and dislocated kidneys. He believes that the enteroptotic habit is more pronounced in late childhood than in early life, and that displaced stomachs are exceptional in early childhood, that is, up to twelve or fourteen years of age. Richard R. Smith (3) found by dilating the stomachs of fifty-seven children that the lower pole was well up in the abdomen, and in fact he found there was no lowering of the lower border of the stomach which could be called a prolapse. He believes with Holznchte and Hulst that the lower border of the stomach should be in the region of the level of the pylorus, that is, about the second lumbar vertebra. He states that the prolapse of kidneys, stomach, colon, and intestines, which accompanies the enteroptotic habit of adult life, is not found in childhood except in rather rare instances. Goldthwait and Brown (4) state that normally the lower border of the stomach is about on a level with the second lumbar vertebra, but that the position of the abdominal viscera may be greatly modified by the posture which may be assumed by the individual. They also state that if the body is not held erect,
the diaphragm must be depressed and the abdominal wall relaxed, allowing the stomach to sag. They describe the type of child with visceral ptosis,

and give the description of a poorly nourished child, with a flat chest, drooping shoulders, an prominent scapula, the spine being rounded in the dorsal region and flat in the lumbar, with a protuberant abdomen—in other words, a child with a round back, forward shoulders, prominent lower abdomen and flat lumbar spine. It is also stated, in discussing the treatment, that "the posture commonly assumed by the individual is a definite factor in the relative positions of their viscera." Gold-
the greater curvature was invariably below the umbilicus. Groedel, in thirty-six men and fifty-four women having no gastric disturbance, found the average distance of the lowest point of the lower border below the umbilicus was one inch for men and two inches for women. He believes that in the treatment of these cases there will be fewer attempts to elevate and support stomachs, since so many formerly considered prolapsed are now known to be within their normal limits. In addition, certain students of this subject have taken the ground that the body formation or posture is the principal cause of ptosis. Coffey (8) states that medical men take the ground that in most cases ptosis is due to malnutrition, neurologists that it is due to a central nervous condition, orthopedic men that it is due to body malformation, Lane that it is due to the erect position of man, which has caused overstretching of the peritoneal supports of the abdo-
minal organs. Coffey also states that the normal stomach in the erect position comes just below the umbilicus. This sketch of the literature gives you an idea of the diversity of opinions as to the normal location of the stomach and how indefinite this location is. Some say that it is or should be at the second lumbar vertebra; others that it should be at the umbilicus, and others that it may be below it. There is apparently no uniformity of opinion in regard to this point.

I am not going to discuss in this paper the already well known embryological and anatomical theories of the causation of ptosis, but will add that it is a commonly stated fact that about one person in five is born with a congenitally defective support of the colon and stomach (4, 6, 8), which may obviously lead to a greater or lesser degree of ptosis. I am, however, going to try to show you that posture in children has apparently very little, if any, influence on the position of the stomach, or even the degree of ptosis in children, regardless of what influence it may have in adults, as will be brought out by the facts I am going to produce, and also that we must revise our ideas as to the normal position of the stomach in children in the erect position, regardless of their good, indifferent, or bad standing attitude.

In the examination of these eighty-three children a definite routine was followed, and the following points were observed and noted: Age, sex, development, height, weight, nutrition, development, shape and capacity of thorax, width of costal angle, index of Bescher and Lenhoff, classification of posture, condition of abdomen (pro-
tubérant, nonprotruberant, or flat), dislocation of kidneys, x rays of stomach following a bismuth meal with child in erect position. The posture varied in these children from a good one, that is, a position where the shoulders were in normal relation to the thorax, the abdomen was not protru-
berant and the physiological curves were normal, to those cases where all of these conditions were exaggerated in one case, or where some one or two characteristics varied from the normal.

METHODS OF EXAMINATION.

Before taking up the study of these cases in detail it might be well to state that there were eighty-three children examined according to the previously mentioned routine, of whom sixty were girls and twenty-three were boys. These children varied in age from four to eighteen years, the average age being about ten or eleven. The height was noted and taken in the usual way by means of a vertical rod. The weight, state of nutri-

---

Fig. 5.—Class 2. Patient is well developed; sag generally; stomach very low. Age, 13: height, 61½ inches; weight, 162½ pounds; thorax, lower part contracted; costal angle, normal; chest capacity, 1½ inches; index, 72.

---

Fig. 6.—Class 2. Patient standing. Age, 13: height, 55½ inches; weight, 96½ pounds; thorax, normal; costal angle, normal; chest capacity, 1½ inches.

---

Fig. 7.—Class 2. Same patient as shown in Fig. 6, but patient is lying down. Note change in shape and position of stomach.
tion, and general body development were also observed, besides the attitude and the size, shape and capacity of the thorax, and the shape of the costal angle. In every case I tried to palpate the kidneys, but was unable to do so in any case, regardless of the relaxation of the abdominal wall or the degree of ptosis of the stomach. No attempt was made to outline the stomach by palpation or by inflation with gas, for it was felt that this was a rather unsatisfactory and unreliable method.

The position of the stomach was determined as accurately as possible by means of the x rays in the following manner: The child was given to drink about 2 1/2 or three ounces of bismuth subcarbonate, stirred up in a glass of water. Immediately following this he was put in front of the x ray tube and about eighteen inches away from it, standing in his usual erect attitude, with the back to the tube, which was on a line with the umbilicus so as to prevent if possible any distortion. The plate usually pressed lightly against the abdomen. Very short exposures were made. Following this in some cases a picture was made of the child lying on its face with the plate underneath, so as to get a picture of the stomach in that position. No attempt was made to put a coin on the umbilicus or to mark it in any way, for it seemed a rather indefinite landmark, and that a more reliable and constant relation could be obtained by using the crests of the ilia for purposes of comparison. On account of the difficulty of getting these children to report again within twenty-four hours no attempt was made to get a record of the colon. Besides showing the position of the stomach in these cases, the height, weight, development, and nutrition were also observed, for these points are said to be of importance in connection with ptosis. A number of the children were frail, with poor musculature, little body fat, and were under size and weight for their age, while others were well above the average. The averages for the different groups by age, height, and weight show children well up to and in some instances above Holt’s averages for children of similar ages. They cannot then be called as a class either underdeveloped or nourished in relation to their ages, so that they must then, so far as these conditions hold, be called average normal children. Of the girls, forty-seven were well developed and nourished and thirteen were poorly developed and nourished. Of the boys, twenty-one were well developed and nourished, and two were poorly developed and nourished. This condition of good development and nourishment is of importance in view of the theory.
that ptosis may be partially due to the lack of proper physical development and a proper and adequate amount of body fat. As far as I was able to observe, general conditions and body weight, with or without much adipose tissue, had very little to do with the position of the stomach. Many children who were very well nourished had quite as much ptosis as others who had no signs of fat about them, and in fact there could be no rule established in regard to this point. The so-called "enteroptotic habit" observed in adults is seen in children, often also the so-called "carrying posture," where the whole trunk is thrown back from the hips, but it does not follow that in these cases one is to expect a ptosis. It may or may not be present, and one cannot tell until an adequate examination is made.

The Thorax.—The shape, capacity, and development of the thorax is supposed to play an important part in visceral ptosis. Here again children and adults differ markedly. In this series the capacity of the thorax was measured relatively by the chest expansion, which averaged as follows:

For 60 girls ... 1.64 inches
For 21 boys ... 1.86 inches
For 81 cases ... 1.7 inches

This shows a relatively good average chest capacity. In some of the cases there was noted a long, flat, narrow thorax, but there was quite as apt to be a stomach relatively high in these cases as in others with a normal thorax. A number of these cases with a contracted thorax showed a normal or relatively great chest capacity as compared with those of the normal type, and no relation could be established in regard to the shape or capacity of the thorax with the degree of ptosis present or to be expected. There was no relation between the size and shape of the thorax and the posture. The costal angle in these cases was generally normal or broad, in spite of the occasional flattening of the ribs, or contraction of the lower portion of the thorax, as is I believe true of children generally, which is also a point of difference from observations on the adult.

In the study of the literature, especially in Smith's (3) articles, it was noted that great stress was laid upon the so-called index of Bescher and Lenhoff, the determination of which was supposed to give one an adequate idea as to the relative capacity of the upper abdomen. This index is obtained by dividing the jugulopubic distance by the waist measurement, taken just around the lower ribs, and multiplying by 100. This gives one a purely relative index, and the higher the index the less the capacity of the upper abdomen is supposed to be. This has been done
on nearly every case in this series, and has proved to be rather a failure.

Indices over eighty are supposed to represent a condition of relative incapacity of the upper abdomen, whereas indices under eighty represent a normal capacity of this area. A study of the indices of this series of cases showed the following facts: The average index of 50 girls was 80, the average index of 23 boys was 75, and the average index of 73 cases was 78, or normal. These data show a relatively normal average index for this series. The average and individual indices for the cases of the individual classes of posture showed that very little reliance was to be placed on these data as a guide to the presence or absence of visceral ptosis. Cases often with the highest indices showed no other evidences which would suggest ptosis, and others with low or moderate indices varying from 57 to 80 showed all degrees of ptosis. There could be no definite lines or relations established between the index and the shape, development, or capacity of the thorax, or shape of the costal angle. In fact, I feel very strongly that no one type of posture can be said to represent or indicate ptosis, which I believe can only be determined by an adequate x ray study of the stomach following a bismuth meal. The relative value of this index may work out satisfactorily in adults, but for children I feel that it has proved to be of little use or value.

THE POSITION OF THE STOMACH IN RELATION TO THE POSTURE.

We come now, after having covered the other point in our inquiry, to the classification of posture. We can study these cases in relation to the position of the stomach. They were classified as follows: 1. Good or so called normal posture. 2. Forward shoulders, normal dorsal curve increased backward and normal lumbar curve increased forward, abdomen protuberant. This type is commonly called the forward shoulders, round hollow back type. 3. Cases in this class showed the forward shoulders, the increase backward of the normal dorsal curve, but had a normal lumbar spine and a flat abdomen. 4. Cases in this class were selected because of the predominating feature of a flat back, that is, the normal physiological anteroposterior curves of the spine were all flattened.

Taking these now in order I will endeavor to show you how little posture in general affects the condition or degree of ptosis, regardless of the other point previously covered.

Class 1. Posture Good. Twelve cases. The cases comprising this class were supposed to represent normal types of children in all respects, that is, in regard to posture, development, and nourishment. The fact that they did so is shown by the following figures:

The average age of this class was 10 years, the average height of this class was 55 inches, the average weight of this class was 68 pounds. Comparing these figures with Emmett L. Holt's averages for the age of ten, we find that these children were three inches taller and two pounds heavier, showing that they were well above the normal average.

The index of Bescher and Lenhoff average 79 + for eleven cases, being a normal index.

The average chest capacity was 1.81 inches, which is satisfactory. Some children had as much as three inches chest expansion, and the lowest was one inch.

No connection could be observed between the development of the thorax or the shape of the costal angle and the position of the stomach. In fact, the child which showed the greatest chest capacity and a broad costal angle, showed also the greatest degree of ptosis, that is, a stomach of the sink drain type, with the lower border four inches below the crests. Out of twelve cases in this class, ten had the lower border of the stomach well below the crests of the ilia, and the other two showed the stomach at the top of the crests in one case, and at the lower border of the fourth lumbar vertebra in the other. The shape of stomachs varied consid-
erably, although the most persistent type was that of the sink drain variety, and while they were generally all dilated, a few were more horizontal and near the normal size.

Class 2. Forward Shoulders, Round Hollow Back, Protuberant Abdomen. This class represented the largest group of cases, forty-five in all, comprising eleven boys and thirty-four girls, whose ages varied from four to eighteen years. The average age was 9.5 years, the average height fifty-five inches, and average weight sixty-four pounds, giving one a moderately average better average for these various conditions than Holt gives for the same age. The index of Bescher and Lenhoff varied from 93 to 57. There were two cases with an index of 93, in one case the stomach being at the top of the fifth lumbar vertebra, and in the other at the lower border of the fourth lumbar, while in the case with the index at 57 the lower border of the stomach was also opposite the fifth lumbar vertebra. These three children were respectively aged nine, twelve, and four years, and were normally developed except for the child aged twelve, who was under weight for her years. The average index for eleven boys of this class was 76, and for twenty-eight girls was 80, while the average index for thirty-nine cases was 79. The average chest capacity for forty-four cases was 10.0 i inch.

The marked predominating features of this class were the round back, forward shoulders, and protuberant abdomen, with the element of hollow back generally present. Now, an analysis of the position of the stomach shows that in sixteen cases the lower border was just above the crests, that is, in the region of the fourth lumbar vertebra, in seven cases just at the crests, and in twenty-two cases was well below the crests, in some instances as much as three or four inches. The size and shape of the stomachs in general impressed me. A good many seemed large and rather dilated, and presented either a dilated horizontal appearance, or were of the sink drain variety. There were very few of the so called normal cow's horn shape, and none of these was normal in position.

This class then represents a condition of so called ptosis of the stomach in practically every case, if we are to consider the second lumbar vertebra as the normal landmark for the lower border of the stomach.

Why is this? Goldthwait (5) states that this posture of forward shoulders, round hollow back, and protuberant abdomen is one of two distinct types commonly met with which cause this condition. To quote from his paper, he states that "in the forward bend of the upper body, or the consequent increase of the anterior curve of the dorsal spine, there is a compensatory increase in the lumbar curve, lordosis, with the protrusion of the lower abdomen forward. In this change the pelvis maintains its normal position and relation to the legs, but as the upper part of the lumbar spine moves backward, as it must in the position of lordosis, the depressions into which the posterior viscera rest are consequently deepened, and as far as this feature alone is concerned there is less liability of the organs becoming displaced downward than is normal. Since, however, this feature is only one part of the support of the viscera, and since the anterior abdominal wall is of much importance in this support, it is evident that as this position necessarily means relaxation of the abdominal muscles, a definite portion of the normal support is lost. It is also evident that as in this position the abdominal cavity, as well as the entire length of the trunk, is shortened, the viscera are naturally crowded downward. In this shortening of the trunk the anteroposterior diameter of the abdomen is necessarily increased, and with this increase of the diameter the diaphragm must be stretched anteroposteriorly, with the result that it becomes flatter and the upper part of the dome is lowered. Since at the back the diaphragmatic attachment extends down to the last rib, and since the liver rests directly against this posterior portion of the diaphragm, if the dome if the diaphragm is flattened it must result in forcing the liver and stomach forward and downward, lifting them out of their normal positions in the spaces at the sides of the spine in the curve of the ribs."

Now, as shown by a study of the average height, weight, and indices of the cases of this class, these children represented nothing abnormal except posture, and many of them, as shown by their photographs, were not extreme types. Coffey (8) has shown that this so called kidney or visceral shelf averages an angle of 51 degrees from the vertical, is four inches deep and takes up 30 degrees of the weight of the organs resting on it, which surely represents an adequate slope to hold almost anything. He compares the abdominal wall to a strip of wood along the edge of a shelf as seen in china closets. Surely now if this slope is increased backward, increasing the angle 51 to a greater one, any relaxation of the abdominal wall must be compared with a removal of such an edge as has been described, and which would of course be then unnecessary, so that as far as the relaxation of the abdominal wall goes, I think we can safely dismiss it from our consideration. Any question as to the flattening of the dome of the diaphragm I believe may be answered by noting the normal chest capacity and development, with a normal index. The influence of such a flattening I believe is more theoretical than real. The average indices and chest expansion were well within normal limits, and the costal angles not narrowed, showing a normal relative capacity of the upper abdomen and a good chest development, so that we cannot attribute such ptosis as existed to these conditions, and as the degree of ptosis was no more marked than in the cases of class 1, representing normal individuals, we cannot properly attribute the ptosis to the posture, but can only state the stomach was lower than has been supposed to be normal, and that not one case had any symptoms referable to it. The cases of this group studied in regard to the comparison of the normal weight and height for their age, with the presence or absence of ptosis as compared to the crests of the ilia as landmarks, showed that four patients below weight had ptosis, two patients below height had ptosis, and six patients both below weight and height had ptosis, and five were without ptosis if the fourth and fifth lumbar vertebrae were taken as landmarks. Of the patients above
weight one showed no ptosis, two above height had ptosis, and thirteen patients above both weight and height for their age showed ptosis, while ten showed none.

Class 3. Forward Shoulders, Round Back, Abdomen Flat.—The cases in this class differed from those of class 2, as far as posture was concerned, only by virtue of the fact that they had a flat abdomen, and no hollow back. In all there were fourteen cases, eleven girls and three boys. The average age of the eleven girls was thirteen, the average height fifty-seven inches, and the average weight 82.7 pounds, being about normal for height, but ten pounds under weight for Holt’s average for the same age. Of the three boys the average age was ten, the average height 52½ inches and the average weight sixty-two pounds, showing as compared with the normal average for ten years a greater height and four pounds less weight. The average chest capacity for eleven girls was 1.75 inches and for three boys was two inches. The average index for twelve cases was 80, nine girls giving an index of 82 and three boys one of 76.

One girl considerably under height and weight for her age, with an index of 90, and a slightly flattened lower thorax, showed a large stomach with its lower border at the middle of the fourth lumbar vertebra, and lying down at the third lumbar. The fourth lumbar was the highest point any of the stomachs reached in the erect position in any of the cases of this class. The majority of the stomachs were apparently large organs, and as has been true in all of the cases studied, some were of the sink drain type and some of the horizontal type, and many are of the so called midline ptosis class, but many are also seen well to the left, apparently resting well within the iliac fossa.

A number of these children exhibited the so called carrying posture or position, which, however, did not seem to affect their degree of ptosis. One patient was fitted with a supporting corset, and x rays before and after fitting the corset were compared, showing that the corset tended not only to raise the stomach slightly, but also altered its shape somewhat. I might add, however, that the corset was applied not for the correction of the ptosis but to improve the general posture. The case with the lowest index, 69, a boy aged twelve, normal in height and a few pounds below the average weight, showed a horizontal stomach one inch below the crests. This class then showed an average ptosis of the stomach to a point well below the crests, with flat abdomen, differing not at all from the observations noted in the other previously mentioned classes.

The examination of the stomachs showed that in this class there were nine below the crests, one at the crests and four at the fourth lumbar vertebra. The presence or absence of ptosis cannot be inferred by the presence or absence of a flat or protuberant abdomen. I believe that such a condition is of relatively little importance in children.

Class 4. Flat Backs, with or without Round Shoulders, and with or without Flat or Protuberant Abdomen.—There were twelve cases included in this class, five girls and seven boys. The average index for the boys was 73, and for the girls 81, the average total index being 78. The average age for the five girls was ten, the average height fifty-one inches, and the average weight fifty-six plus pounds, showing an average height, but a few pounds under weight for the normal. Of the seven boys the average age was nine, the average height seventy-one plus inches, and average weight seventy-nine plus pounds, showing a considerable increase over the normal average in height and weight for that age.

There was an equal degree of ptosis for each sex, the two greatest being respectively in a boy aged eleven, well above height and weight and with an index of 72, the lower border of the stomach being 2½ inches below the crests, and a girl aged ten, being both below height and weight, but with an index of 78, and a stomach 2½ inches below the crests.

An analysis of the position of the stomach in these cases in relation to the crests of the ilium showed that eight were below, three were at the level of the crests in the region of the lower border of the fourth lumbar vertebra, and one was at the fourth lumbar, with the child lying down in the only picture I was able to get of this case. The actual amount or degree of ptosis was no greater in this class than existed in any of the other classes, as far as I could see.

The posture represented by this class is the second type spoken of by Dr. Goldthwait (5) as a cause of visceral ptosis. He believes that the absence of the compensatory increase in the lumbar curve or its entire obliteration is a cause of visceral ptosis, due to a change in the normal axial relations of the abdomen and pelvis, and so causing an obliteration, partial or otherwise, of the kidney shelf. At the same time decreasing its angle of slope, to which I have already called attention, and because of this making more of a direct pull on to the visceral supports. It would seem then that if any one class of individuals was to have ptosis greater in frequency and degree than all others this would be the class. This has not proved to be so in this study. Neither was there a greater degree of ptosis in these cases, nor was it any more frequent than a study of all the previous classes has shown it to be in them.

Conclusions.

Now what has this investigation shown? Namely, that in these eighty-three cases, of generally average developed children, the average position of the stomach is a much lower one than had been previously suspected, and that to find a stomach at or well below the crests of the ilium is not at all unusual. But one of these children had symptoms which were due to a dilated colon, which condition caused chronic constipation, and not to a stomach which showed a moderate ptosis. They were otherwise perfectly well as far as their digestive apparatus was concerned. We must also, I believe, change our ideas as to the shape of the child’s stomach. As seen in this series it was generally large and either horizontal or of the sink drain type. The ideal so called cow’s horn stomach was rare. Finally, I would state that I do not believe that posture in children, apart from the erect po-
sition of humans in general, has nearly as much
to do with ptosis as has formerly been believed.
What I believe has been shown proves that the
child’s stomach is lower than we generally sup-
posed, and to find a stomach low in a child does
not therefore mean that there is a pathological ptosis
It is of course obvious that poor posture should
be corrected and impaired general health built up,
but I believe that neither is a cause of ptosis in
children, nor that a low stomach is necessarily a
weak link in the chain of a child’s development.

THE CLIMATE OF SAN DIEGO, CALIFOR-
NIA, REGION, WITH RELATION
TO RENAL DISEASES.*

By P. M. CARRINGTON, M. D.,
Surgeon, U. S. Public Health Service.

INTRODUCTION.

One of the objects of this Association being the
study of climatology, its founders were obviously
of the opinion that climate has an effect on the
incidence of disease, and therefore must have a thera-
petic value in the treatment of disease. Much of
the literature of climate in recent years has dealt
with the subject from the standpoint of the value
or lack of value of climatic treatment of tuberculo-
sis, but other diseases are affected (beneficially,
some of us believe) by suitable climates, and among
such diseases chronic nephritis in its various forms
may be classed.

Most of us who extol the excellencies of the cli-
mate of some particular locality are, in a measure
at least, prejudiced by personal benefit received,
by pardonable local pride, or by personal interest.
The writer belongs in the first class, having recov-
ered from a tuberculous infection in New Mexico,
and afterward having derived great benefit from a
two years’ residence in San Diego, where he was
sent to recuperate from an attack of nephritis.

Our opinions as to the value of this or that cli-
mate are largely empirical, being based chiefly on
clinical experience. Still, a study of mortality
statistics throws some light on the subject, and, if
confirmatory, strengthens our convictions and fixes
our opinions. It has been said that figures do not
lie, but that lies sometimes use figures. I do not
accuse our statistics of mendacity, nor acknowledge

*Read at the Thirty-first Annual Meeting of the American Climato-
logical Association, held in Washington, D. C., May 6, 7, and 8,
1913.

myself mendacious; still, in considering mortality
statistics, with reference particularly to the chronic
diseases, some corrections or explanations are ne-
necessary to make them tell the truth, for in our sys-
tem of collecting vital statistics no provision is
made for charging back to the locality of origin
deaths of transient residents, from diseases con-
traced elsewhere than at the place of death, so
that in the Southwest, for instance, where large
numbers of consumptives resort, the death rate
from tuberculosis is high, although the climate of
that region is a most favorable one for consump-
tion.

Geographical and General.—San Diego, California,
at the present time a city of between seventy-
five and one hundred thousand population, is located
on the shores of the bay of the same name and the

Pacific Ocean, in north latitude about 32°, and
about seventeen miles north of the Mexican border.
That portion of the town along the bay and ocean
front is but little elevated above sea level, but the
main portion of the residential section is built on
hills and mesas, ranging from one to two hundred
feet in elevation, and separated by many canions
leading into the bay; thus giving the city a most ex-
cellent natural drainage.

The character of the soil is such (being composed
largely of decomposed granite on hills and mesas,
and sandy loam in the valleys), and the drainage
so excellent, that there is practically never standing
water or mud, even after the heaviest rains. Fif-
ten miles inland we strike the foothills, and a lit-
tle farther east the southern part of the Sierras,
which in this latitude rise to an altitude of fifteen
of fruits, berries, and vegetables thrive during the greater part of the year, and the adjacent waters supply a variety of edible fish (all very important factors in the dietary of nephritics), while the city is furnished with an ample, unfailing supply of pure mountain water, and an excellent sewage system assists in maintaining the exceptionally good sanitary condition of the municipality. The entire county of San Diego is traversed by a recently completed system of good roads, built at an outlay of $1,250,000.

History of Weather Observations and Some Opinions of the Climate.—The government has corps of the army, which was intrusted with such matters until the Weather Bureau took charge of all meteorological stations in 1891.

For the past fifty years the meteorological instruments, although their location has been changed several times, have been located within a radius of one half mile, so that in estimating the character of the climate we have not only the advantage of long continued observations, but also, for the last fifty years, observations made under practically unchanged conditions. Noninstrumental weather observations, indeed, extend back to 1542, when Cabrillo entered San Diego Bay and recorded its ex-
excellent qualities as a harbor of refuge from the southwestern gales, and Father Junipero Serra, who established the first California mission at San Diego in 1769, praised the climate, which he said reminded him of that of Spain.

Richard Henry Dana, in his *Two Years before the Mast*, published in 1835, gave an account of the early days of this region, and recorded his observations of the climatic conditions. Alexander Agassiz visited San Diego in 1872, and said, speaking of the climate: "This is one of the favored spots of the earth, and people will come to you from all quarters to live in your genial and healthful climate—a climate that has no equal." General A. W. Greeley, while head of the Signal Service, United States Army, wrote:

The American public is familiar on all sides with elaborate and detailed statements of the weather at a thousand and one resorts. If we may believe all we read in such reports, the temperature never reached the eighties, the sky is flecked with just enough of cloud to perfect the hot days in summer, but great heat is prevented by two factors: During the forenoon in summer a low lying cloud, locally referred to as the high fog, but spoken of by the Spaniards as "el velo que cubre la luz del sol," or "el velo de la luz," "the veil which covers the light of the sun," or "the veil of the light," tempers the heat of the day until the trade winds, blowing from the ocean, dispel the cloud which is no longer necessary because of the cool breeze. The temperature goes as high as 90° F., four hours in a year, and as low as 40° F. for ten hours. The mean maximum ranges from 62° F. in January to 75° in August, and the mean minimum from 44° in January to 63° in August and September. The annual rainfall of San Diego is ten inches, and occurs during the so-called rainy season, which extends from October or November until March. The humidity is relatively high, ranging from 67 in December to 80 in July, with a mean annual of 75. Occasional temperatures of 100° F. have been recorded. These high temperatures occur during the so-called desert winds, but at such times the relative humidity is very low, ten per cent., or even as low as three per cent, having been recorded.

I will not bore you with statistical tables, but briefly, the extremes of temperature in San Diego are 101° F. and 32° F.; the average of the three consecutive warmest days was 82.9° F., while the average of the three coldest days was 40.2° F., recorded in September and January, respectively. In a period of twenty-five years the thermometer was lower than 80° F. on an average of 304 days a year, while the average daily range of temperature during the same period was 13° F., and the average difference between the mean of one day and the next is 2° F. The sun shines in San Diego on an average of 356 days a year, and the proportion of possible sunshine is sixty-eight per cent., and the equability of the sky, the nights ever cool. There is possibly one place in the United States where such conditions obtain; a bit of country about forty miles square at the extreme southwestern part of the United States, in which San Diego, California, is located.

*General Characteristics of the Climate.*—In general, the climate of San Diego is characterized by uniformity of temperature, the average daily range being from 10° to 12° F., and the variation between winter and summer being less than 20° F. There is also a high proportion of sunshine, which is even more constant in winter than in summer. Very hot and very cold periods are infrequent, high winds are unknown, and fogs are of less frequent occurrence than in the average sea coast locality. The climate may be described as cool in summer and warm in winter, and the short range of the temperature is due partly to the latitude, partly to proximity to the sea, and the absence of mountains in the immediate neighborhood contribute to infrequency of cloud or fog.

In this latitude one would naturally expect very

---

*Fig. 4.—Coronado tent village, San Diego, Cal.*

landscape, the breezes are always balmy, and the nights ever cool. There is possibly one place in the United States where such conditions obtain; a bit of country about forty miles square at the extreme southwestern part of the United States, in which San Diego, California, is located.1

1Quoted by Carpenter.
temperature is the characteristic of the climate to which your attention is particularly invited.

Mr. Ford A. Carpenter, a corresponding member of this association, and for sixteen years in charge of the Weather Bureau at San Diego, summarizes the climate as follows:2

**Temperature.** Since the beginning of meteorological records the temperature has averaged less than one hour a year above 90° F. Highest and lowest temperatures ever recorded are 107° F. and 32° F., and no snow has ever fallen, although the records extend back to 1871.

**Rainfall.** The annual rainfall averages ten inches. Back from the coast the rainfall increases to over forty inches. It is in this well watered region that the magnificent water supply of San Diego is located.

**Wind.** The sea breeze keeps San Diego cool in summer and warm in winter, and the nearby mountains and desert give it a dry marine climate. The wind averages five miles an hour throughout the year.

**Sunshine.** The sun shines in San Diego on an average of 356 days a year. The photographic sunshine recorder shows that for twenty years there has been less than nine days a year without one hour or more of sunshine.

Comparative Seasonal Temperatures. Temperatures are usually shown on a globe by lines which pass through regions of the same degree of heat or cold. Red lines of 60° F. or 70° F., showing the summer temperature at San Diego, also enclose Alaska and Siberia. Blue lines of 50° F. and 60° F., showing the winter temperature at San Diego, enclose Egypt and Arabia. Thus San Diego may be said to have Alaskan summers and Egyptian winters.

Climatic Prevalence of Nephritis.—Dickinson has shown, with relation to Great Britain and Wales, that deaths from renal diseases increase with the variability of the temperature in the various parts of the kingdom, ranging from one nephritis in fifty-three from all causes in Aberdeen, with an annual mean temperature of 47° F., and a mean monthly variation of 30.7° F. to one in 487 in Shetland, where the mean annual temperature is 43.8° F. and the mean monthly variation 19.9° F. On the western coast, by reason of the influence of the Gulf Stream, the winters are warmer and the summers cooler, and a fairly uniform temperature prevails throughout the year. On this coast diseases of the kidney are less frequent by one half than on the eastern coast of England, bathed by the cold waters of the North Sea, where the summers are much hotter and the winters colder than on the Atlantic shore, and where there is a wider range of temperature and greater variability of climate; and he attributes the extreme infrequency of renal diseases in the Shetland Islands to the uniformity of the temperature, notwithstanding its comparative low range. He says:

Renal disease, putting aside that of lardaceous origin, is the companion of wheat and barley, rather than of the vine and of the olive. It abounds wherever the climate, however cool during the winter, is warm enough in the summer, as in Canada, to bring wheat to perfection; and becomes scarce where oranges and lemons grow, and where deciduous trees, as generally characteristic of the scenery, are replaced by palms and other tropical endogens. It may be stated that the figures given by Dickinson refer to the year 1863, when diagnosis was

---

The Climate and Weather of San Diego, Cal., by Ford A. Carpenter.
indicative of actual health conditions; the mortality rates for some sections thus showing, for some of the chronic diseases, higher percentages than local conditions justify, by reason of the large numbers of invalids resorting to those localities. If it ever becomes possible to require every physician to keep complete records of all cases of disease and injury treated, as hospitals now do, and make periodical reports to the health authorities, then we shall have correct and complete morbidity and mortality statistics. In the registration area of the United States, the proportion of deaths from nephritis to the total mortality for 1909 is one to fifteen and sixteen one-hundredths, this including both urban and rural rates. In New York city the proportion is one to eleven; Philadelphia, one to ten; St. Louis, one to 11.29; and in general, it may be stated that the rate is high in cities having a very variable climate, subject to great and sudden changes. Herrick, in Osler's Modern Medicine, says:

The relative infrequency of this form of nephritis (chronic interstitial) in the warmer climates has been frequently noted. This may be in a measure accounted for by the fact that in the warmer climate there is less exposure to cold, inclement weather, and sudden changes of temperature. He advises resort to a warmer climate in winter and to a cooler one in summer for nephritics.

Now, the proportion of deaths from nephritis in San Diego to the total from all causes is one in eighteen, but eliminating from consideration deaths from nephritis occurring in persons who had lived in San Diego less than twelve months, the proportion is one to forty-three. The Board of Health in San Diego has no data as to the length of residence in the persons who had been there more than twelve months before death, but, based on experience of local physicians, few or none occur in residents. This, on the face of it, while establishing the fact that nephritis is not relatively of so frequent occurrence in the climate of San Diego as elsewhere, does not seem to prove the excellencies of the climate in the treatment of the disease, but we must consider that, if one desires to be benefited by climatic treatment, one must resort to the desired climate before the disease has completely demolished the structure of the organ for which relief is sought; since no remedy, climatic or otherwise, is capable of restoring or replacing tissue which has already been destroyed, and it is the common experience of all climatic resorts that a vast majority of patients come after their organs are irreparably damaged.

Bullard, of Los Angeles, in his work on Apparent and Actual Mortality, written in 1893, showed that twenty-five per cent. of those dying in Los Angeles from nephritis had come to California within two years in an advanced stage of the disease, and the experience of San Diego physicians shows that the proportion of imported cases is much larger in San Diego at the present time; which is supported by the mortality statistics of the San Diego health office above referred to. To state the matter in somewhat different form, the death rate in the entire registration area as shown by the census reports for 1909 was 1,440 per hundred thousand of population; from Bright's disease, 95.2, and from pneumonia and other diseases of the respiratory organs, 178.5. During the same year in the entire State of California the corresponding figures were 1342.8, 85.3, and 144.3. For the State of New York, 1566.2, 127.5, and 226.8. For the city of San Diego, 1594.2, 86.9, and 161.3. These are the uncorrected figures, no allowance being made for nonresident decedents. The rates for pneumonia and other respiratory diseases are given to show the comparative infrequency in San Diego of these diseases, which are often intercurrent causes of death in the subjects of renal disease. Figures of this character might be multiplied indefinitely, but enough have been quoted to show that climate does play a part in the causation of renal diseases, although I do not mean in any sense to minimize the other well known causes, nor even to assert that unfavorable climatic conditions may have a preponderance of causative action.

Advantages of the Region for this Class of Diseases.—The first and chief advantage of this climate in renal disease lies in its equability and uniformity, not only as between night and day, but as between the different seasons, there being no sudden drops in the temperature, and the difference between summer and winter temperatures being greatly less than is frequently experienced in the Mississippi Valley and on the Atlantic Coast in a period of twenty-four hours. As a consequence of this uniformity and equability, there is a relative infrequency of the acute respiratory and intestinal diseases, which so often in less favorable climates become the intercurrent cause of death in nephritis. Since the climate is one suitable for and favorable to nephritics during the entire year, it becomes possible for these patients to remove with their families to this region, establish homes and settle permanently, thus avoiding the separation from family and homesickness, which are so often inseparable from climatic resorts.

While the climate of San Diego is such as I have described, there are two other distinct climates different from that of the immediate coast within a distance of forty or fifty miles from the city of San Diego. One is the climate of the mountainous district some twenty miles inland, which is characterized by warm summers and cool winters, with a considerable daily range of temperature, moderate day-light rains, low relative humidity, fairly heavy winter rains, and some thunder storms during the summer. Another twenty miles eastward we have a distinct desert climate, with its almost unvarying sunshine, warm winters, and with great variation between day and night temperatures, hot summer days, extremely low relative humidity, and almost no rainfall. So persons resorting to the San Diego climate may readily and easily avail themselves of a temporary change without traveling great distances, and at trifling expense.

Reference to Some San Diego Cases.—My friend, Dr. P. C. Remondino, for nearly thirty years a resident of San Diego, who has written very extensively concerning the climatology of Southern California, says: 'A well man will stand less chance of ever becoming sick here, and an invalid will, on the average, live longer and more comfortably and with the greatest possible and probable chances of
ultimate recovery, than in any other portion of the United States."

Two of the prominent physicians of San Diego went there on account of nephritis, one sixteen and the other six years ago. The first was apparently in a very advanced stage of the disease, with general anasarca, ascites, and great general debility, and was physically unfit for the least activity. In such cases we must use the expression "cured" with great caution, but this gentleman is now doing a very large practice and is very active in many ways, and is to all appearances, intents, and purposes a well man. Another very pronounced case is that of a gentleman sent to San Diego sixteen years ago on account of nephritis, and, as his medical adviser said to me, "completely water logged," and who for several years has taken a very active part in the political life of the community; he is to-day a vigorous and apparently healthy man. These are but a few examples of the scores of well known citizens whose cases are equally striking.

It is a climate which necessitates no seasonal change of clothing, where neither great heating nor cooling is required at any season, and where vegetables and some fruits grow during the entire year, making proper diet for nephritics easily obtainable. In such a climate attacks of diseases invited or influenced by change of weather, diet, or clothing, must necessarily be reduced to a minimum, and Dr. Remondino says: "I know from observation that a weak heart and defective kidney will support work better here than in the East."

CONCLUSIONS.

Experience shows, and the opinions of those whose judgment we must respect support the proposition that renal diseases are more prevalent in climates subject to great and sudden changes of temperature, and where other causative factors are practically the same as in regions where such diseases are less prevalent. Vital statistics, while not so conclusive, in general bear witness to the same facts. The experience and testimony of our confrères in localities of equable climate is to the effect that nephritics do well, feel better, live longer, and even, in some cases, seemingly recover in climates of which San Diego presents an example. That a part of the observed beneficial effect may be due to more sane modes of living is admitted, but both reason and experience persuade us that the even climate must be credited with an influence in the general good results, even though the exact proportion of its influence is not demonstrable. For the official figures of meteorological observations used in this article, as well as for many other facts, I am indebted to the work of Mr. Ford A. Carpenter on the Weather and Climate of San Diego.

THE DIFFERENTIATION BETWEEN MORONISM AND IGNORANCE.

By Howard A. Knox, M. D.,
Ellis Island, New York,
United States Public Health Service.

This problem is one that has never arisen in this country until recently, owing to the fact that our excellent school system has reached every one and educated him, if this was possible. If he were incapable of acquiring knowledge then that fact classed him as a mental defective. At the present time the great influx of uneducated aliens renders it necessary in justice to ourselves and to them,

![Diagram](image_url)

FIG. 1.—The author’s "Cube Imitation" Test. This consists of four large and one small black cube. Beginning on the left, the examiner moves the small cube, as shown by the dotted lines, and the subject is asked to do what the examiner did. The examiner's movements are slow and deliberate. A study of a large series of cases has shown that high grade imbeciles can imitate line (a) but not (b), that feebleminded can imitate line (b) but not (c), that morons or higher feebleminded imitate line (c) but not (d), that normal persons can imitate line (d) and that only bright persons can imitate line (e). This test was developed at Ellis Island, and is one of the most valuable single performance tests. This standardization is for illiterates over twelve years of age: a, High grade imbecile; b, feebleminded; c, moron; d, normal; e, bright.

FIG. 2.—This is the "G" test or geographical puzzle, and it is a valuable test since in attempting to fit the pieces into their proper places the defective demonstrates that muscular inco-ordination, limited sense of admissibility, and lack of decision which are often seen in defectives, and hence aid in their detection.
other attributes, the following: Didactically, originality, ingenuity, the power of prolonged attention, and the ability to cooperate intelligently if not accurately with the examiner. They also possess a natural moral tone and finesse, regardless of whether these have been taught or not. The tests evolved and made use of at Ellis Island at the present time are intended to, and probably do, show a presence or absence of these characteristics.

The following is a general method of examination for aliens over twelve years old, which is applicable to almost any illiterate for the purpose of determining whether or not he is feebleminded, and to be classed as a moron. Educated persons, of course, should be tested by means of the ordinary Simon-Binet scale.

1. The first point to determine is whether or not, in dealing with foreigners, the subject and the interpreter understand each other perfectly. When this is determined to the satisfaction of the examiner, he should question the subject with a view to finding out, what he knows and remembers of the ordinary occurrences and everyday duties of his previous environment; for instance, if he was a farmer, ask about the farm, if a tailor, ask technical questions about that trade, and so on, suit the questions to the calling and method of living. Further than this, ask about conditions in the place from which the subject came.

2. Determine what the subject remembers about his journey, whether he knows the names of the large cities through which he passed, and whether he knows the name of the ship he came on.

3. Is he well oriented for time, person, and place?

4. Has he ordinary facts of common knowledge, such as the number of days in a week and months in a year, with their names?

5. Can he meet the ordinary little emergencies of life? What would he do if tempted in various ways? Would he avoid trouble and questionable things? These points should be determined by special questions suited to the age, sex, and standard of living in each case.

6. If he can count forward from one to twenty, he should be able to count backward from twenty to one.

7. He should be able to remember and repeat, after ten seconds, five figures.

8. He should be able to obey three simple commands, and he should be able to touch with a pencil, after the examiner, four like objects such as dice or cubes, skipping any one and jumping back to any one; this latter is the “C. 1...” or cube imitation test. (Fig. 1.)

9. After looking at an ordinary picture containing a dozen objects for thirty seconds, he should be able to name six of them from memory.

10. He should be able to copy a diamond or a square with a lead pencil.

11. He should be able to arrange in the order of their weight five cubes of different weights.

12. He should be able to do the “G” or geographical puzzle in two minutes and twenty seconds. Defectives nearly always attempt the impossible in doing this puzzle, and they thereby show that they possess but a small sense of the “fitness of things.” Clumsiness and incoordination are also shown, and these are important since nearly all defectives possess them to some degree. (Fig. 2.)

13. The “F” or Healy-Fernald test should be accomplished in three minutes, and the “H” or the Healy puzzle in fifty-five seconds. (Fig. 3.)

These thirteen elements of the examination can be gone through within twenty minutes, and repeated on the following or subsequent days if desired, and when this is done the examiner is quite well acquainted with his subject and is in a good position to give him a mental rating. If he makes a total failure of four of the thirteen of the examination as given here, he should be considered in the moron class, provided a reasonable attempt has been made to instruct him, in points that could not be accomplished at the primary examination. This examination will seem, to one who has not worked with alien defectives, rather easy, but experience has shown it to be the hardest, that is in all ways fair to the illiterate immigrant. (Fig. 4.)
I wish to add one word of caution, and that is to be certain that the case of moronism is of congenital origin, and not a simple transient condition due to anemia and toxemia, as in uncinariasis, to pellagra, to other toxines, to hypothyroidism or disturbances of other internal secretions, and lastly, and by far the most important, to psychogenic depressions. These transient conditions, which may simulate true congenital moronism or feeblemindedness, are in the main curable, and it would be unjust to certify and deport such a person. It is therefore very essential that all such examinations be conducted by persons with medical training.

THE USES AND LIMITATIONS OF PARAFFIN IN THE TREATMENT OF OZENA.

By Julius Auerbach, M.D., New York.

This paper is based on the study of thirty-two cases of genuine ozena. The writer's primary object was to note the effect of paraffin injected subcutaneously or subperichondrially into the nasal chambers; such injections have been done by our European colleagues, and they have reported brilliant results from its use.

It becomes evident that one must start with some definite ideas as to what constitutes true ozena. If, as some authors assert, Grunewald, Noebel, and others, that it is a disease secondary and dependent upon an accessory sinus empyema, and does not exist per se, the logical view to take is that one which would be directed to the treatment of the primary disease; other authorities, and they are not a few in number, recognize ozena as a disease beginning in the nasal mucous membrane, and if accessory sinus disease is present, that it is secondary to the atrophic rhinitis. Others, again, are of the opinion that the presence of empyema of the accessory sinuses is but a coincidence.

The nature of the process is as yet not fully explained. Sufficient anatomical material is on hand to show that we are dealing with an inflammatory process, but from the vast amount of literature on the subject it may be seen that the causes leading to the pathological changes have not been made clear. How the disease begins is another question; one which is a large and tempting problem in itself, but which it is not the purpose of the writer to take up. Here, too, battles are being fought between those who regard a distinct organism as the etiological factor and those who assert that it is but an advanced condition of hypertrophic rhinitis. It is not easy, from the mass of conflicting statements, to draw conclusions as to the origin, or as to the primary or secondary nature of the disease; in fact, many of the strong adherents of one theory or another believe that the element of doubt is considerable for each. Loewenberg and Abel look upon ozena as an infectious disease, the former, in 1885, having described the diplococcus which he could differentiate from the pneumococcus. He was able to immunize mice against the pneumococcus, while he could infect those animals with the ozena coccus. Abel could demonstrate his ozena bacillus in one hundred cases, as could von Polsen his Bacillus mucosus fatidus. Strubing is of the opinion that the microorganisms entering the nose set up a catarrhal inflammation of the mucous membrane, leading to hypertrophy, with atrophy as an end stage.

Empiric treatment of disease is not taken up enthusiastically in this day of serums and specifics, and justly so, unless it can be shown by actual results that such treatment is accompanied by marked benefits. That the paraffin treatment of ozena will some day be shown to be crude and unscientific I do not doubt, but that time will be one in which the bacteriological obstacles have been overcome, and a specific serum or vaccine has been evolved. Coldera and Gaggia made serological examinations from extracts of ozena crusts, and in none of the examined ten cases was there a complement fixation with the blood serum; from this the authors conclude that the excitant of ozena is not a specific one.

I have attempted in each of my cases to find a localized pus focus, where possible, and to note whether treatment directed to the foci tended to influence the atrophy, with its manifestations of crusts, foul odor, etc. This, in itself, puts a severe test upon the examiner, who must use every diagnostic measure at his command, and must subsidize his olfactory sense in the painstaking efforts to determine the origin of the secretion. Hajek, in his discussion of the relation between atrophic rhinitis and accessory sinus empyema, holds that in all instances there will be found a pus focus somewhere, and that where this is not found, our diagnostic measures are at fault.

I shall precede the account of my own cases in this paper by a short description of the disease under discussion. The most pronounced symptoms are those for which the patient generally seeks relief, namely, the fetor and crust formation. The former, in advanced cases, is characterized by a detestable odor, which has been compared by some to the odor of sweating feet, by others to the odor of crushed bed bugs. Certain it is that it is atrocious enough to be long remembered when once inhaled, and to make its possessor a menace to society. It can be detected not only when within close range of the unfortunate, but even when removed from him by a considerable distance. In early cases the fetor has a sweetish, depressing character. In women the fetor becomes more pronounced during the menstrual period. At times the odor of ozena is similar to that of tertiary luetic nasal affections accompanied with bone necrosis. The odor from accessory sinus empyema is different. Freese's chemical analysis of the secretion taken from ozena patients found it to be highly alkaline in reaction, rich in indol, skatol, phenol, sulphureted hydrogen, and fatty acids.

Next to the fetor, the crust formation is the most bothersome symptom to contend with. The former, in fact, is dependent upon the latter, and the crusts still further, by their mechanical presence, set up a syndrome of symptoms, consisting of difficulty in nasal breathing, headache, anosmia, dryness of the
throat, etc. According to Zarnicko, the freshly removed secretion is free from odor. Juraz states that the odor sets in only after the secretion has been allowed to stagnate for some time. One sometimes meets with cases where the interior of the nose is free from secretion, yet the odor is present, even pronounced. In these cases a postrhinoscopic examination will reveal adherent crusts in the nasopharynx or in the posterior part of the middle or inferior meatus.

Rhinoscopic examination of typical cases, after the removal of the crusts, discloses the anemic, atrophied turbinal bodies, although in many instances the middle turbinate is found in contact with the septum and occluding the olfactory nisue. The atrophy is most marked in the inferior turbinate; sometimes the middle turbinate is so atrophied that the region of the hiatus semilunaris is freely exposed. Sometimes, also, the atrophy permits a full view of the anterior wall of the sphenoid sinus with its ostium; the posterior wall of the nasopharynx comes particularly into view, and allows the inspection of the tubal musculature during speaking or swallowing. On postnasal examination, one finds the mucosa dry and shiny, or covered with tenacious yellow or greenish mucus.

That my cases may all come under the definition of genuine ozena, as given by Frankel, I have not included cases of accessory sinus empyema or cases having local areas of suppuration which are accompanied by atrophy and crust formation, and which in many instances cannot be differentiated from the true type of ozena. Of great value in determining the origin of the secretion in the nose is the method of tamponage of Gottstein; the middle meatus being closed off by small pledgets of cotton tightly placed upon the other, the secretion originating from the antrum of Highmore, the anterior ethmoidal cells, or the frontal sinus should not be able to gain access to the inferior meatus. In true ozena the lower meatus will still be found to contain secretion, and this, if allowed to stagnate, forms into crusts.

The use of paraffin in surgery was first suggested by Corning, and was practically demonstrated a few years later by Gersuny. Numerous followers have used it with various degrees of success in cases of umbilical hernia, prolapse of the rectum and vagina, prolapse of the uterus, incontinence of the bladder and rectum, and in cases of facial deformities, as in depressed noses; also in facial hemiatrophy and to fill in depressions following the radical operation on the frontal sinuses. That it was not altogether free from deleterious consequences was soon evidenced by reports of collapse following its use, and in some instances sudden blindness due to embolism. The literature is rich in reports of cases where untoward effects were noticed. Pfenannstiel reports a case of combined cerebral and pulmonary embolism after the injection of a mixture of hard paraffin and petrolatum for incontinence of urine. Halban also reports a case of lung embolism following the injection of petrolatum for prolapsus vaginae. Kofman, upon injecting twenty c. c. of petrolatum for prolapsed vagina, observed a coughing spell while the patient was still on the operating table, with exitus twenty-four hours later from embolism. Gersuny reports two cases of embolism. Broeart reports slight lung embolism following injection of paraffin for ozena. Leiser, after injection of a mixture for saddleback deformity of the nose, witnessed the onset of blindness of the left eye due to thrombosis of the ophthalmic vein. Hurd and Holden report a similar case, with blindness coming on directly after injection of semisolid paraffin for a nasal deformity. Ophthalmoscopic examination disclosed an embolism of the central retinal artery.

An analysis of the above cited cases discloses that invariably soft paraffin or a mixture of soft and hard paraffin was used, and it has remained for Eckstein to prove that where hard paraffin of high melting point is used embolism never occurs. Eckstein himself has given thousands of injections, and in no instance has embolism resulted. It therefore becomes evident that in the selection of paraffin it becomes of supreme importance to use hard paraffin (hard at the temperature of the room) and of a high melting point (50° to 52° C.). It is conceded that this form of paraffin is difficult to handle, and that specially constructed syringes have to be used, but its efficacy has been proved, and, with the improved syringe of Mahu and Brunnings, its manipulation becomes comparatively easy.

The use of paraffin in ozena is based partly on the theory that the abnormal width of the nose has something to do with the stagnation of the secretion, and that by the mechanical narrowing of the nasal cavity a stronger expiratory current may be made to take place, and so aid in the expulsion of the secretion. It has been noticed that when ozena exists in unsymmetrically developed noses the narrower side contains fewer crusts than the wider side. Broeart thinks that paraffin has a trophic influence on the mucous membrane; he has shown that a regeneration of the sclerotic mucous membrane occurs, and that the epithelium takes on its natural characteristics. It is also thought that this trophic influence is brought about by the mild inflammatory reaction set up by the paraffin and by the stretching of the tissue fibres.

Technic.—Next to the proper selection of the paraffin, the syringe plays a very important rôle in the proper carrying out of the injection. The writer employs hard paraffin of a melting point of from 50° to 52° C. Of the numerous syringes on the market, all enjoying certain special advantages over the others, and among which may be mentioned that of Onodi, Harmon Smith, Yankauer, Botey, and Mahu, the writer prefers that of Brunnings, which is powerful, adaptable to the use of hard paraffin, easily manipulated with one hand, allowing proper localization of the paraffin and, by the notch arrangement, prevents overinjection. The last advantage is a very important one, not only in the intranasal use of paraffin, but also when used for cosmetic purposes, as in cases of saddleback deformity, where many failures may be attributed to overinjection; and this, not because of lack of judgment as to the amount to be injected, but because of the difficulty in propelling the paraffin and the consequent use of excessive force.

The paraffin, after having been melted in the hot water bath, is drawn primarily into the Eckstein...
syringe (glass barrel insulated with thick rubber), and then forced into the barrel of the Brunnings; the piston is next introduced, and the syringe is then worked very much after the manner of the trigger on a pistol. With each pull of the trigger, one drop of paraffin is expressed; when the paraffin hardens in the syringe, it no longer appears in drops, but in the shape of a thin strand. The needle which fastens on to the syringe is then dipped into hot, sterile water, and the paraffin again liquefies. However, as soon as it strikes the tissues it again solidifies, and so is prevented from entering the circulation. The keynote to success lies in thoroughness of aseptic technic. Of over three hundred injections given by the author, he met with but one case of infection; here septal abscess took place.

After thorough cleansing of the nose, with the removal of all the crusts, the nasal mucosa is anesthetized with a ten per cent. solution of cocaine; no ephedrin is employed, as it causes shrinking of the mucous membrane. The writer carries out the injections with the patient in a sitting posture. A self retaining speculum is introduced, permitting the index finger of one hand to guide the needle while the syringe is manipulated with the other. The amount injected varies; the best guide is the appearance of the mucous membrane; this is to be raised until it is seen to be almost white. The site of injection may be the mucous membrane of the inferior turbinate, the septum, or the floor of the nose. Where sufficient paraffin is not injected under the mucous membrane of the inferior turbinate to bring about a narrowing of the nasal cavity, or when the mucous membrane is so friable that it will not retain it at all, other sites must be sought; the septum, the floor of the nose or the outer nasal wall, between the inferior and middle turbinate. In fact, one must seize the opportunity to inject into any available tissue in the nose. The most difficult place for injection is the floor of the nose, on account of the concavity of the region.

The writer employs no preliminary incision of the mucous membrane, and, where possible, injects both sides of the nose. Often the cartilaginous septum is found so atrophied that the needle will easily perforate it, and one finds himself injecting the opposite side. Weleminsky, after injecting with Schleid solution, makes an incision in the septum about one c.m. in length, separates the mucous membrane from the perichondrium, and introduces the paraffin into this newly made space. Luber's raises the mucous membrane by injection with normal salt solution, and then proceeds with the injection of the paraffin.

Clinical Observations.—From within three days to a week after injection there is produced a change in the character of the secretion; it becomes more liquid, is less tenacious, there are fewer crusts, and the patient, in spite of narrower nasal chambers, seems to breathe more freely; soon the crusts disappear almost entirely, and little effort is required to clear the nose. This improvement lasts for a variable length of time—from two to five months. Whether the improvement is due to the narrowing of the nasal chambers or to the trophic influence on the mucous membrane I cannot say; probably both are factors. In the author's cases the average time

which the paraffin was retained is four months. Ten cases have retained it for five months; the majority about four months. The writer knows of no other treatment that will give the same improvement for the same length of time without the persistent cleansing and removing of the crusts. The amelioration of the disagreeable symptoms, notably the fetor and crusting shortly after injection, is, in most cases so marked that the delight of the patient is only equalled by the enthusiasm of the operator; but alas! the delight and enthusiasm are both of short duration, because it is not long before the dreaded symptoms reappear.

Out of thirty-two cases of genuine ozena treated by injections of paraffin in the past year and a half, twenty-six were markedly improved for months following the injections, with absence of foul odor and crust formations, and no other treatment, local or general, was instituted. Six cases could not retain the substance in the slightest degree, and no beneficial results were manifest. I must say, however, that these were extremely advanced cases, with the mucosa so friable that it tore with the introduction of the first drop. In five cases of my series one side was used as a control, while the other was injected, and then both sides compared. The injected sides in all these cases showed, after the lapse of a week to ten days, a marked improvement over the noninjected sides. Eventually both sides were injected. The number of injections for each patient varies; where the mucous membrane has still retained its resiliency, two or three injections along the septum, floor, or outer wall are necessary to bring about a narrowing of the nasal fossae. In more advanced cases, when the mucous membrane has become sclerotic, I have made as many as twenty injections before any appreciable reduction in the calibre of the fossae was noticed. The writer met with septal abscess in but one case; the paraffin was spontaneously cast off, and the abscess was treated in the usual way. Five patients complained of rather severe frontal headache, which lasted for one day following the injection. One patient complained of pain over the left eye; this subsided in twenty-four hours. In one case there was slight swelling and discoloration of the lower lid. The bleeding is practically nil except where injections are made into the septal mucosa, and here it is generally so slight as to require no special consideration.

Brindel and Broccart were the first to use paraffin as a therapeutic measure for ozena, and both reported favorable results. Of the ten cases treated by Blau with injections of paraffin, he reports five that had been under observation for from one and a quarter to two and a quarter years, as entirely free from crusts and foul odor. Three cases showed but a slight amount of crust formation, though the fetor was entirely absent. Two of his cases did not respond to treatment. S. Wetterstand also injected ten cases of ozena, with paraffin, and reports healing (cure) in three, and improvement in seven. Boley reports twenty per cent. perfectly cured from the functional standpoint, and forty-five per cent. curable but not absolutely cured. Clayton Fox has found that all his patients have been cured or relieved from the fetor and crusting.
To illustrate the results of my observations, I will cite the histories and behavior of a few cases.

Case I. Mary V., aged sixteen years, for the past three years had had a disagreeable odor from the mouth or nose, which she herself was unable to notice; it her attention was first called to it by her parents, and then she noticed that her schoolmates would keep at a safe distance from her. Every day she would expel large greenish crusts from both sides of her nose. Lower turbinate was injected for external notable, pale, expel crusts, no nasopharyngeal injection.

Polypus of left inferior meatus was seen; mouth breathing, palate hypertrophied, septum obliterated; tubal musculature plainly visible during the act of swallowing. Transillumination showed antra and frontal sinuses clear, light reflexes present; washings from both antra showed crusts.

Both nasal cavities were injected with hard paraffin at intervals of two weeks. Calibre considerably reduced by the artificial spur made on the septum and by injections under the mucous membrane of the inferior turbinates. Patient observed every day for a week following the injection. Crusting on injected side gradually diminished; odor less. After injection of other side, same improvement noticed; within three weeks after the first injection, was free from odor, and crusts were considerably diminished; could breath through nose without trouble; no washings or sprays. At end of three months, slight odor again noticed, crusts assuming larger size. Examination disclosed disappearance of the paraffin from the inferior turbinate. Again injected, and patient remaining free from disagreeable symptoms for four months. Received eight injections in all.

Case II. J. T., aged twenty-four years, a barber by trade, chiefly complained of crusty and dryness of the throat for many years. Had had several intranasal operations performed for dryness in breathing; headache over left frontal region; great difficulty in expelling the crusts, which form chiefly on the right side. Examination showed septum deviated to the right; right middle turbinate hypertrophied and in contact with the septum. Lower turbinate pale, atrophied, and covered with mucus. Left nasal cavity filled with large crusts, with mucoid secre
tion in the olfactory fissure; middle turbinate moderately enlarged; nothing left of the inferior turbinate; odor pronounced. Observed every day for a week following the injection. Hard paraffin injected into the nasal wall and floor; mucous membrane of septum very friable and could not retain the slightest amount. Injections given in three sittings at intervals of one week; improvement noticed after each sitting, and continued strong; nose free from symptoms for three months. The paraffin at the end of that time no longer found in the outer nasal wall, though the floor was still raised by the mass. Had repeated injections, which relieved him for about four months; no other treatment employed. At last sitting had again to inject the floor.

This is a case of so-called unilateral ozena, but which nevertheless had all the characteristics of the usual bilateral variety, except that on the side of the narrow nasal chamber there were no crusts. How much the trauma of the previous nasal operations contributed to his present condition it is hard to estimate. I have frequently seen atrophic rhinitis set in after the complete removal of the lower turbinate, although no less an authority than Freer states that he has never seen atrophic rhinitis as a consequence of removal of the inferior turbinate, and thinks that the disease has a distinct pathology which cannot be surgically treated.

Case III. Miss S. K., aged seventeen years. Since childhood had had large greenish masses come out of her nose, and she had been told by members of her family that the odor existing from her person was sickening to this I could personally attest. Her nose was abnormally wide and flat, especially in the middle third, but did not present a characteristic saddleback deformity. Marked atrophy of all the intranasal structures; the sphenoidal ostium of the left side plainly visible, and the sinus could be probed with ease. On account of the marked atrophy of the middle turbinate and bulla ethmoidalis, a catether could easily be introduced into the frontal sinuses; washings from this region, as well as from both antra, showed crude fluid.

Injection, hard paraffin into every available space; improvement began at once; at end of ten days fetor entirely disappeared, as well as the crusts; patient elated. Hard paraffin injected externally for ten days; note straight profile resulting. This patient received no set-back for a period of five months, during which time she was frequently observed. At times small crusts could be removed from the floor of the nose posteriorly, but they were not nearly of the dimension with which they were before injection. She received only three injections altogether.

Case IV. W. K., aged twenty-eight years. Referred to me by Dr. George K. Hildreth. For the past three years had had difficulty in removing large greenish foul smelling crusts from both nares; sense of smell very markedly diminished; no previous operations on nose. Throat dry; voice husky. On examination, both nasal cavities found filled with greenish yellow crusts, after removal of which the floor of the nose still contained a tenacious yellow mucus of foul odor. Inferior and middle turbinates found atrophic. Hiatus semilunaris easily probed. Clear fluid from washings of frontal sinuses and antra. Both nasal fossae injected at same sitting. Improvement, lasting three months, with return of the difficulty with which they were before injection. That he had been under observation received four injections.

Case V. Mrs. L., aged forty-eight years. Since child had a sticking discharge from the nose, with formation of large crusts. Great difficulty in nasal breathing, and throat dry; voice weak. At times, after considerable hawking, would expel greenish mucus from throat. Skeleton of the nose atrophied; nose was broad, flat, and occupied the whole space of the face. The crusts were so large that it could be easily pushed with the probe from one side to the other, very much as one is able to do with septa that have been resected. She had never had any operation performed on her nose. Both nasal fossae injected at same sitting. Left nasal fossa retained the paraffin on the lower border of the inferior turbinate and on floor. On the septum the paraffin made its exit from the point where the needle entered. In the right nasal fossa, no retention possible on account of the extreme friability of the mucous membrane. Improvement, lasting about three months on the left side. Repeated injections given on the right side, with no success.

Case VI. Miss F. J., aged twenty-one years. Very pronounced case; atrophic condition advanced; just a ridge left of the inferior turbinate. Under observation since August, 1912. Received twelve injections, with no influence on the condition.

Case VII. M. F., aged eighteen years. Moderately well advanced case of ozena of four years' duration. Under observation fifteen months. Both sides injected at one sitting. Showed improvement shortly after injection. About a month following the treatment had severe attack of influenza; when he reappeared, the protheses were no longer in place, and he said that the crusting had returned. After second injection improvement again noticed. Gets relief for about four months.

Case VIII. H. E., aged eighteen years. Seen through the courtesy of Dr. I. W. Voorhees. Pronounced odor, crusty, and atrophy. No focal supplicative area. Protheses introduced into both nasal fossae and the chambers narrowed considerably; could inject considerable quantity of paraffin, the mucous membrane being quite thick. Bleeding from point on the septum where needle was introduced. A few hours after injection patient experienced pain in the left eye, and lower lid became swollen and red. Several days later, redness and discoloration of lid were no longer present, but slight tenderness was found over the orbit; after the use of cold applications this had disappeared by the following day. Has relief for about four months, after which time returns for infrequent injection.

Conclusions.

1. In the injection of hard paraffin of hitherto pointing the danger of embolism is eliminated.
2. The results so far obtained even in severe cases afford encouragement for the further use of paraffin injections in ozena.

3. It is impossible to speak of a "cure," even in those cases which show a disappearance of the disagreeable symptoms.

4. There is no influence anatomically on the atrophied structures.

5. Functionally the results are all that can be desired, though all cases eventually require reinjection.

TRAUMATIC PERIOSTITIS OF THE LUMBAR SACRAL SPINE.*

By Clarence C. Coon, M. D.,
Syracuse.

During the past few years a lot of attention has been given to the diagnosis of lesions of the spine and particularly the lower lumbar and sacral region. As a result of this study and demonstration it has become an accepted fact that most backaches present some definite lesion. If in this brief paper, we confine our observations to the lower lumbar and sacral areas and also take into consideration only those backaches due to trauma, we will still find many cases in which a positive diagnosis of a definite lesion is not always easy. Many of these patients will present the characteristic symptoms of sacroiliac strain or displacement; in such, the diagnosis is not often difficult. Others will give evidence of a fracture, and the x ray will show a fracture of a transverse process of the fourth or fifth lumbar, a fracture involving the body of the vertebra, an articular process, some part of the neural arch, or a fracture into the sacroiliac articulation. Because of the severity of injury, in this class of cases, the symptoms presented will often be confusing, and accurate diagnosis is impossible without the x ray.

Dislocation of the fifth lumbar vertebra or spondylolisthesis, is, I believe, not as common as fractures in this region.

Abnormalities of the fifth lumbar vertebra and of the sacrum must not be overlooked; while of themselves they may not be the primary cause of backache, yet in the presence of an injury such abnormalities may exert a powerful influence. Dislocation of the articular processes of the fourth and fifth lumbar and of fifth lumbar and sacrum also occur.

If we also exclude for the present these cases in which there is a clearly demonstrable lesion we still have many backaches of the lumbar-sacral region which occur after an injury, and the symptoms are often very persistent, and it is in these cases that it is often so very difficult to make a diagnosis between something and nothing—to know whether the patient is a malingerer or not, and particularly is this so, when called upon to testify as a witness in court in a negligence action.

During the past year I have been called upon to examine fifteen cases, in which none of the lesions cited above could be demonstrated.

In a general way all of these patients complained of pain in the lumbar-sacral region, all had muscular spasm, preventing free flexion of the lumbar spine. Some had localized paralysis, anesthesia, or hyperesthesia; in none was it possible to demonstrate any abnormality of the bone, either congenital or as the result of trauma.

In this series of cases in which the diagnosis seems fairly accurate, examination was requested not less than one month after the injury. Twelve of the series were examined during the first year, and three after one year. In all cases a careful x ray study was made in addition to the clinical examination.

CASE I. E. F., man, aged thirty-five years, fell from a scaffold a distance of twelve feet, six weeks previous to examination. He injured his right arm and back and was in the hospital four weeks, unable to move without assistance, on account of pain in back. At present all movements of the lumbar spine are extremely limited. Muscular spasm and hyperesthesia, more marked in the left lower extremity, patellar reflexes exaggerated. X ray showed hazy outlines in the region of the fifth lumbar vertebra. Same characteristics shown on plates at reexamination several days later.

CASE II. Mrs. D. S. Patient was quite stout. Injured seven months previous getting off trolley car while in motion. She fell and rolled down an embankment, receiving injuries to the kidneys, rectum, and the back. At present there was some pain in lower back. All movements of the back were sharply limited. An unusual amount of lumbar lordosis existed for a fatty patient. Anesthesia of outer x ray showed indistinct and irregular outlines of the fifth lumbar vertebra and the top of the sacrum. There was some evidence of callus formation.

CASE III. Mr. H. C. B. Injured fourteen weeks previously by being caught and doubled up between two freight cars. He was in the hospital four weeks, and had been unable to work since the injury on account of pain in the small of the back. There was tenderness on pressure in the fifth lumbar region. No anesthesia or hyperesthesia present. All movements of lower lumbar spine were restricted. The x ray outlines of the fifth lumbar vertebra and the top of the sacrum were not clear.

CASE IV. Mr. M. J. Injured nine and one half months previously, by falling from a scaffold a distance about twenty-three feet. He landed in a sitting position. He was unable to move either lower extremity for five weeks. He had not good control of the muscles of right lower extremity at the present time. The left extremity seemed all right. No sensory disturbance except pain in the back. He stood with an absence of lumbar lordosis. Attempts to restore the normal curve caused severe pain. All movements of the back were limited. The x ray showed a marked irregularity of the outlines of the right side of fifth lumbar, and of the upper part of sacroiliac articulation, with a possible fracture of the transverse process. The left side of the vertebra was cloudy and indistinct.

CASE V. Mr. C. A. H. Injured two months previously by being hit in the back by a truck which fell from a truck. The patient was doubled up as he fell. He had a lot of pain in his back and thighs. The movements of the lumbar spine were limited in all directions. The patient was rather stout and had more than an ordinary amount of lumbar lordosis. There was tenderness on pressure in the fifth lumbar region.

X ray examinations were made on different occasions during one month, in an effort to make a positive diagnosis. Each time the exposure was made at a different angle, stereoscopic, etc. The outlines of the fourth and fifth lumbar were not clearly defined.

CASE VI. Mr. A. W. Fell into a furnace hole, nine months and three weeks previously, striking on his back.

*Read at the meeting of the Lake Keuka Medical and Surgical Association, held at Keuka, N. Y., July 17 and 18, 1913.
and side. He passed blood and pus in his urine for a time. He complained now of pain in the back and rectum. There was tenderness on pressure over the fifth lumbar vertebra. The back flexion was about half normal.

The x-ray showed a fuzzy appearance of the transverse processes and of the left side of the fifth lumbar vertebra.

CASE VII. Mr. E. E. L. Injured three and a half months previously. He fell about fourteen feet and injured his back. He was unable to use his right lower extremity for about four weeks. He complained of prickling in both feet. The patellar reflexes were very much exaggerated. The patient stood with a decided list to the left. The flexion was very tender on pressure over the fifth lumbar vertebra. The movements of the back were very limited. Right lateral flexion was entirely absent.

An x-ray and tilting test seemed to indicate a fracture of the left side of the body of the fifth lumbar vertebra. The outlines were very indistinct.

CASE VIII. Mr. H. M. P. Caught in an elevator one month previously. For about ten days he was unable to turn over in bed on account of severe pain across the back and hips. Three days after accident both lower extremities felt prickly and numb. During the first week any attempt to move the legs would produce spasm and pain in the muscles of the back and hips. At present there was no impaired sensation or motion in the legs. The patient stood with a list to right. There was tenderness on pressure in the lower lumbar region. Forward and right lateral flexion of back were fairly free. Left lateral flexion was very limited. Repeated x-ray examinations failed to show fracture. The right side of the fourth and fifth lumbar vertebrae very indistinct. The left side less so.

These brief reports of cases are fairly typical of the others of the series observed. A routine examination, as to posture, movements, impaired nerves, etc., was made in each case. The abnormalities only are here noted. A majority when examined showed little or no deviation of the spine. Spasms of the hamstrings were not marked, and were usually present about equally on each side. The symptoms common to all are entirely subjective and consist of pain, tenderness, and limited motion. No constant objective symptoms could be found except the evidence offered by the x-ray plates, and these seemed to present the same general characteristics in each of the series, viz., the cloudy, fuzzy appearance of the bones in the painful area, and this was interpreted to mean that because of the injury the ligaments and periosteum were injured, and the resulting inflammation, aggravated by more or less constant use of the part, had produced a condition allied to callus formation, and that there was a considerable deposit of lime salts in the tissues immediately surrounding the bone; that because of the irregular distribution of this deposit, being more dense near the bone, the x-ray outlines of the bone were invariably obscured, and it was impossible, even with repeated examinations, to get a clear, well defined shadow of the bones of the injured area; at the same time, and on the same plate, the bones above and below the painful area produced a clear and well defined shadow. This cloudy appearance could not be shown in cases examined less than one month after the injury, which seems to agree with the x-ray appearance of callus formation in bone-injuries elsewhere. Much might be written of the frequency of injuries to this part of the spine, as to its causes, etc., but if we have in mind the anatomy of the part and know something of the direction of the force applied at the time of injury it will be readily seen that this part of the spine is very liable to be injured. And in this series of cases the force which produced the injury was not sufficient to cause a fracture or dislocation, but had produced a stretching or tearing of surrounding ligaments and periosteum, and in the process of repair, nature had deposited some lime salts.

This calcareous deposit cannot be demonstrated until about one month after the injury, but when present helps to explain why many of these backaches are so persistent.

In the early cases studied, I supposed that the x-ray appearance of this area might be due to faulty technic in making the plates, or to some condition of the patient such as thick abdomen or collection of feaces. Many cases were repeatedly examined at different angles, after catharsis, etc., and, after all precautions were taken, there still remained the hazy and ill defined outlines. The interpretation of these plates must be made from the original negative with correct light, and reproduction by any process, either on paper or glass has failed to bring out the detail and for that reason I am unable to present prints from these negatives for your inspection.

The treatment of these cases can be stated in one word—rest. Given a patient complaining of pain, tenderness, and inability to move freely, with a history of previous injury, and a series of x-ray plates showing more than normal obstruction to passage of light rays, I think we are justified in making the diagnosis of traumatic periostitis.

RETROPHARYNGEAL ABSCESS.

By W. C. Billings, M. D.,
Surgeon, United States Public Health Service, in Charge Medical Division, Immigration Service, Angel Island, California,

AND J. G. Wilson, M. D.,
Acting Assistant Surgeon, United States Public Health Service; Clinical Assistant, Nose and Throat Department, New York Polyclinic Hospital.

There is a rather prevalent belief that retropharyngeal abscesses are seldom encountered except in children, and that cases of the vertebræ due to cervical Pott's Disease is the chief cause of this condition. That such a belief should be so widely held is probably due to the fact that the condition is often overlooked, except in the cases of tuberculosis of the cervical vertebræ where its possibility is always kept in mind, and where its diagnosis is comparatively easy. It is with the idea of drawing attention to the fact that this disease frequently occurs in adults who have been previously healthy, and that the condition is an extremely serious one when not early recognized, that we report the following case:

J. K., a healthy appearing, strongly built Slovak, aged eighteen years, was admitted to the Immigrant Hospital, Ellis Island, August 5, 1911, suffering from sore throat, which he said was better than it had been a few days previously. There was swelling of the left side of the neck, most prominent at the posterior border of the sternocleidomastoid muscle, and a slight bulging in the rhino-
pharynx, more marked on the left side, and pushing the tonsil on this side slightly forward. By palpation behind and above the soft palate a small area of fluctuation was discernible. On admission it was impossible to procure a history of his case owing to the fact that no interpreter was available. Later we ascertained that he had complained of sore throat and difficulty in swallowing for two days previously. On admission his temperature was 38° C., as were his respiration. A small area of consolidation was noted in the left lung, and it was considered that he was suffering from bronchopneumonia. The pharynx continued inflamed but no area of fluctuation could be made out. On this day, the 15th, an irregular, scattered eruption appeared on his arms, legs, and buttocks. The lesions varied in size from pinhead to that of a dime. They were bright red, and did not entirely disappear on pressure. This eruption came out in the course of twelve hours. His general condition gradually grew worse and we both the day after admission our patient was suffering from septic pneumonia with a toxemic rash. On the 16th, the pharyngeal wall was again bulging a little and there was increased difficulty in swallowing and more pain in the throat.

A free expectoration was noted, the median line of the pharynx and 220 c.c. of foul-smelling pus was withdrawn. The temperature dropped to 37.8° C. by the next morning. The pain and difficulty in swallowing had entirely disappeared. He seemed brighter but was still very weak and prostrated. The rash was now fading and assuming a darker color. On the 19th, a scarlet rash appeared on the chest. There were also noted at this time the presence of lesions in the throat and around the anus, which resembled mucous patches. A Wassermann reaction done at this time was negative. A sigmoid examination was made, and a small abscess was incised. The diagnosis was secondary syphilis. The condition remained about the same except for a gradually increasing prostration and a more marked involvement of the lung until the evening of the 22d, when death occurred suddenly from respiratory failure. The autopsy was negative, except for the evidences of pneumonia in the left lung, which showed involvement of all three lobes.

This case illustrates three points: First, the signs of retropharyngeal abscess may quickly disappear, the pus being dissipated in the loose fascia, and finding its way to some point distant from the original seat of fluctuation within the course of a few hours. Second, the necessity for immediate evacuation the moment the diagnosis is made, as a few hours' delay may make such a change in the picture that the diagnosis becomes doubtful. Third, the extreme gravity of the condition and the danger of complications.

Besides these three main points there are other minor points that are worthy of note. Chief of these is the fact that infection in this case was from a sore throat that was in all probability due to syphilis. Owing to the failure of the Wassermann reaction and the inability to get a good history through lack of interpreters, this point can never be definitely decided, yet the probabilities remain in favor of syphilis.

Another point which has been often emphasized before is that retropharyngeal abscess is especially liable to be complicated with pneumonia. Finally, the case will serve to emphasize the statement we made in the beginning, to the effect that the disease is not one solely of childhood, and that owing to the anatomical arrangement of the parts it is especially liable to give rise to the most serious consequences. Without going into the details of the anatomy of these parts, it will suffice to say that the arrangement of the muscles, fascia, and the lymph glands of this region is such that we may have infection occurring in any one of the following manners:

1. Infection from the middle ear, via the canal for the tensor tympani muscle.
2. Sphenoidal sinus infection.
3. Necrosis of the cervical vertebrae.
4. Direct injury to the pharynx itself.
5. Extension from lymphatic gland involvement; the lymph nodes lying between the anterior surface of the vertebral column and the pharyngeal aponeurosis being especially liable to involvement.
6. Thrombosis or embolism arising in connect with septic processes.

ANGEL ISLAND, CALIFORNIA.

THE BELINORG, EIGHTY-SIXTH STREET AND BROADWAY, NEW YORK.

CYLINDER SHOWER'S, THEIR SIGNIFICANCE.

BY G. R. WILLIAMS, M.D.

PARIS, III.

Diagnoses and prognoses have oftentimes been based upon the count of cylinder casts found in a specimen of urine; and it may be ventured that the cylinder shower, i.e., the sudden increase in the number of these casts, is not without clinical significance.

However, some caution is necessary. For example, I recall the case of a man of fifty, which proved a puzzle to the physician for almost two years. He was termed by many, a neurotic. One consultant, a man of nation-wide authority, assured the family that the trouble lay in the gall-bladder, while another was certain that the diagnosis of nocturnal epilepsy was more probably correct. Sputum, gastric contents, and urine were repeatedly analyzed without additional information being gained. Upon one occasion, more than one per cent. of serum albumin was found in the urine, but this was ignored by the physician. At another date, a tapeworm was secured by the use of pumpkin seed. Suddenly he passed into a typhoid state, and a temperature chart was very suggestive of typhoid. Analysis of the urine at this time showed the presence of dozens of casts in each field, most of them hyaline, but quite a few of them were
Questions for discussion in this department are announced at frequent intervals. So far as they have been decided upon, the further questions are as follows: CXXXVII.—How do you treat threatened abortion? (Closed August 15th.)
CXXXVIII.—How do you treat incontinence? (Closed September 15th.)
CXXXIX.—How do you treat chancroid? (Answers due not later than October 15th.)

Whoever answers one of these questions in the manner most satisfactory to the editor and his advisers will receive a prize of $25. No importance whatever will be attached to literary style, but the award will be based solely on the value of the substance of the answer. It is requested (but not required) that the answers be short, if practicable no one answer to contain more than six hundred words, and our friends are urged to write on one side of the paper only.

All persons will be entitled to compete for the prize whether subscribers or not. This prize will not be awarded to any one person more than once within one year. Every answer must be accompanied by the writer’s full name and address, both of which we must be at liberty to publish. All papers contributed become the property of the Journal. Our readers are asked to suggest topics for discussion.

The prize of $25 for the best essay submitted in answer to Question CXXXI was awarded to Dr. Nelson Du Vat Brecht, of Washington, D. C., whose article appeared on page 475.

---

**PRIZE QUESTION CXXXVI.**

**THE TREATMENT OF CHOLERAM INFANTUM.**

(Concluded from page 527.)

Dr. J. R. McClure, of Newark, Ohio, emphasizes that:

In the treatment of cholera infantum it must be remembered that we are confronted with a case of acute intoxication, with an appalling array of symptoms and conditions, which must be immediately and judiciously handled.

The main indications are: (1) To empty the stomach and intestines; (2) To neutralize the effect of the poison upon the heart and nervous system; (3) To supply fluid to the blood and make up for the very great drain of the discharges; (4) To reduce the temperature; and (5) To treat special symptoms as they arise.

Gastric lavage and colonic irrigations meet the first indication: For the stomach use two teaspoonfuls of bicarbonate of soda to the quart of hot water, giving repeated washings; for the colon, give high enemas of normal salt solution, repeated in two hours. Nothing better for the second indication than the use of morphine and atropine. To a child, two years of age, morphine 1/50 grain combined with atropine, 1/600 grain, given hypodermically, and repeated, if necessary in one hour; small doses frequently administered are much better than a single large dose.

Morphine is contraindicated when there is drowsiness, stupor, or relaxation, when there is a cessation of vomiting or when vomiting is only slight. It is indicated to neutralize the effect of the toxins upon the heart and nervous system; it is therefore an useful expedient for allaying undue excitement, nervousness, vomiting, or purging.

---

granular and minute. The albumin content averaged nearly one per cent. He died within twelve hours after the analysis was completed. A private and incomplete autopsy revealed findings which were not disclosed to the other consultants.

One year later a pregnant woman passed a hydatid mole. She became dropical and drowsy, and passed very little urine. Just as the case seemed hopeless, the urinary output was increased and she appeared to be somewhat better. I was asked to examine some of this urine. It was fairly filled with large, hyaline casts. An occasional granular cast, but no albumin, was found. Twelve hours later not a single cast could be found in the centrifuged urine. The patient rapidly recovered. I could report a similar case of this kind. How may findings of this nature be reconciled with those detailed above? Sometimes they cannot, although a general survey of these cases might confuse, a close study will bring out the fact that these cylinder showers had very few features in common.

Men who have given to the cylinder cast considerable study have been struck with the variations in size, by the relation of the amount of urine being passed when the showers occur, by the relation of edema (if present), by the symptoms, by the persistence of the showers, and perhaps by other coincident urinary findings. Erdman (Journal of the American Medical Association, November 20, 1912) suggests that hyaline casts are produced by the retention of hyaline material in a tubule. He ventures that this form may remain in position until sufficient pressure is established behind to push it on. The idea is not a bad one when attempting to explain the sudden appearance of large hyaline casts where there is an increase of urine, a decrease of edema, and recovery associated with one of these showers. I am not inclined to apply to the grave cases any such principles. Showers in a person dying of Bright’s disease are characterized by casts from the smaller tubules and are essentially degenerative.

The Favorable and Unfavorable Cases.—Elucidating somewhat further, we note that in the unfavorable cases the urine is likely to show no changes in quantity or may be decreasing, that the casts are not huge, but often imperfect and minute, and consist of many granular or otherwise degenerative types, often containing blood cells, renal cells, or pigment.

But the favorable cases show increasing output and monster hyaline casts. When edema is decreasing at the same time, the idea is highly suggestive that the process has been in part a general damming back of the urine.

In the favorable cases, moreover, the cylinder showers are quickly completed; whereas in the grave ones, the casts may persist, or be found to be actually increasing in number so long as urine can be secured. In either instance, the shower probably occurs but once, and may be regarded as a crisis especially in those cases which recover.

The subject of cylinder showers needs further study. It is unfair with our present knowledge to assume that a sudden increase of these elements spells a hopeless prognosis.

109 East Court Street.
Hypodermoclyses of normal salt solution meets the third indication to relieve the extreme thirst and excessive loss of fluid from the blood; about one half pint being introduced into the cellular tissue of the abdomen, thigh or back every eight hours.

For the fourth indication, nothing equals hydrotherapy; cold baths or cold sponging, continued for ten to thirty minutes, and repeated every hour, if necessary, is safe and very effectual in the reduction of temperature. Iced cloths, the ice cap applied to the head, cold or ice water injections, or rectal suppositories of ice may be used where the temperature is not sufficiently lowered by the baths.

The fifth indication may be understood to include a resume of the preceding indications, and the treatment of any other symptoms that may arise.

It is worse than useless to attempt internal medication before the vomiting and purging have abated. After the subsidence of these symptoms thorough purgation by the use of calomel, 1/10 grain, with soda, is administered every twenty minutes, until ten doses have been given. If the calomel is not retained I use one ounce of castor oil, added to four ounces of milk, which has been brought to a boiling point in a double boiler, and fed as hot as can be taken. By securing a thorough evacuation of the bowels, and thereby eliminating the products of decomposition, the bacteria and their toxins, we have taken the first great step in the cure of our little patient.

As a conservator of tissue, but more particularly as a stimulant, brandy or champagne should be given frequently and in small doses. When vomiting does not permit of their use by the mouth, brandy, ether, or camphor may be given hypodermatically.

For cold extremities, or a cold, clammy skin with subnormal temperature, a hot mustard bath or a mustard paste applied all over the body, and hot water bags and bottles placed around the patient, should be used until a suitable reaction has occurred.

Further medicinal treatment consists in the use of an intestinal antiseptic such as the following:

- **R.** Guaiacol, ......................................................................................................................................................... mv;
  - Cupri arsenatis,......................................................................................................................................................... gr. 1/20;
  - Bismuthi subgallicatis, .................................................................................................................................................. gr. ij;
  - Zinci sulphocarbolatis, .................................................................................................................................................. gr. 1;
  - Sodi sulphocarbolatis, .................................................................................................................................................... gr. 1;
  - M. ft. pulv. No. 1.

Sig.: To be given in milk or brandy every four hours.

Of a corrigent consisting of:

- **R.** Hydargyri chloridi mitis, ........................................................................................................................................ gr. 1/20;
  - Pulveris ipecacuanhae, ..................................................................................................................................................... gr. 1/50;
  - Sodi bicarbonatis, ......................................................................................................................................................... gr. 1/2;
  - Bismuthi subnitritatis, ...................................................................................................................................................... gr. 1;
  - Saccharini, ......................................................................................................................................................................... gr. 1/100;
  - Olei anisi, ........................................................................................................................................................................ gr. 1/20.

M. ft. tabella vel pulvis, No. i.

Sig.: One powder, in water, every three hours.

Of an anodyne consisting of:

- **R.** Nicoli bromidi, ....................................................................................................................................................... gr. 1/134;
  - Codiine sulphatis, ............................................................................................................................................................ gr. 1/67;
  - Pulveris ipecacuanhae, ......................................................................................................................................................... gr. 1/134;
  - Lithii carbonatatis, .............................................................................................................................................................. gr. 1/25;
  - Olei anisi, ............................................................................................................................................................................ gr. 1/134.

M. ft. pulvis, No. i.

Sig.: To be administered whenever restlessness, flatulence, or colic indicate.

The subsequent treatment consists of hygienic and dietetic measures, together with general tonics, such as arsenic, iron, nux vomica, and wine. Cod liver oil should be deferred until the stomach and appetite are quite normal and the stools free from mucus. It should, however, be continued throughout the succeeding winter months.

During the acute stage, all food, especially milk, should be withheld, so long as a disposition to vomit continues—for a period of at least twenty-four hours. Thirst may be allayed by giving frequently, but in small quantities, cold whey, thin barley water, or albumin water. If they are refused or vomited, absolute rest will do more than anything else to hasten recovery. After the stomach has rested for twenty-four hours it is generally safe to permit a nursing child to take the breast tentatively. The intervals of nursing should not be shorter than four hours, and the amount allowed not to exceed one fourth the usual quantity. Nursing may be gradually increased, so that in three or four days the usual feedings may be resumed.

In the case of artificially fed infants, a wet nurse should be secured. Where this is impossible sterilized cow’s milk, properly modified, should be used, at first in small quantities, and the effect upon the stools and temperature watched. Later a return to certified milk may be made.

In no disease is a change of air more desirable than in this. As soon as the subacute symptoms have subsided, cold baths are indicated. If living in the city a change to the seashore or to the mountains in the summer, and to a warm equable climate in the winter, will be found very beneficial.

**Dr. Samuel Stalberg, of Philadelphia, holds that:**

In the treatment of cholera infantum we must first take into consideration the attacks. Prompt treatment is imperative. First thoroughly cleanse the whole digestive tract. If there are signs of foreign matter still being in the stomach, i.e., if the vomiting has not stopped, immediately wash out the stomach and give a colonic irrigation of a quart of normal saline solution, at 100° F. Give castor oil, 5i, to a child one year old, other ages in proportion. If the oil is vomited, give calomel, 1/10 grain, with sodium bicarbonate, one grain every fifteen minutes for ten or fifteen doses. Glaufer’s salt in one drachm doses may be used instead. Apply an ice bag to the head, and reduce fever by cool baths and cold packs. For infants under one year, the temperature of the water should be about 95° F. Apply turpentine suppositories for abdominal pain. When pulse is weak or irregular give strychnine hypodermatically, grain 1/400 to 1/200. When there is prostration with other signs of a rapid loss of fluid give an hypodermoclysis of normal saline solution. Caffeine citrate, 1/5 grain, or Siberian musk, one grain, repeated every three hours, may be given if the strychnine fails to benefit. Where there is persistence of the profuse watery stools, with its consequent drain upon the system, morphine, 1/50 grain, combined with atropine sulphate, 1/600 grain, should be given hypodermatically, and be repeated not oftener than once in three hours. The effects of the morphine should be carefully watched, and should be stopped when the purging has been controlled, or there is stupor or drowsiness. When

**PRIZE ESSAYS.**

[New York Medical Journal]
the temperature is below normal the extremities are cold, etc., a warm bath (108° F.) and hot water bottles to the feet are of use. All food and drink should be stopped absolutely. After several hours, when the vomiting has been somewhat controlled, small pieces of cracked ice, or teaspoonful doses of cold boiled water may be placed in the child's mouth. If the water is not vomited it may be given ad libitum, and the little patient usually drinks with avidity. The patient should be kept in a cool place, in the fresh air, and protected from flies, etc. Absolute muscular rest should be enforced. A single loose flannel or cotton garment is sufficient. The arms and buttocks should be cleansed, dried, and powdered after each evacuation. Removal to the seashore often has a wonderful effect in causing immediate improvement.

Later Treatment.—At the end of twenty-four hours, or after the subsidence of the acute symptoms, feeding may be resumed by giving, in addition to the water, barley water, albumin water, or cold whey. The return to milk should be very gradual and not be begun for several days. In the breastfed infant, milk feeding may be resumed earlier than in the bottlefed, but the intervals of nursing should be longer, and only one fourth or one half the usual amount be given. Between the nursings, whey, barley water, or albumin water should be given. In the artificially fed, milk should not be resumed until the bowel movements are free of curds. It is given at first in the form of skimmed milk, one fourth ounce in every second cereal feeding. Then sterilized or pasteurized milk, rendered alkaline by the addition of lime water, and modified to suit each particular case, is substituted. An additional, occasional dose of the laxative, and of the colonic irrigation may be necessary. In making a return to the usual diet, starvation must be guarded against. Ten grains of bismuth subnitrate in solution, or five grains of salol may be given for their astringent and disinfectant effect.

Prophylaxis.—This is of prime importance. First, since the great majority of the summer diarrheal cases occur in the artificially fed, the great importance of maternal feeding as a preventive of infant mortality is realized. Mothers, and even physicians, should be educated to the great importance of encouraging maternal nursing.

Second, keep the baby's intestinal tract in as good a condition of health as possible, by combating indigestion whenever it appears, and especially in warm weather. In the summer all the requisites of fresh air, bathing, cleanliness, should be observed. The milk supply of artificially fed babies, especially during the summer is of the highest importance. The protection of the milk against infection from flies, insects, manure, hairs from the cows, and decomposition from high temperature, is one of the great problems of the day. The proper solution of which will go far toward reducing the morbidity of cholera infantum. The bacteriological count of a given milk is not the only consideration. The proper modification of the milk in regard to its constituents of fat, protein, and sugar, in proper proportions for each child, is of equal importance. In hot weather milk should be sterilized or pasteurized. Bottles, nipples, cooking utensils, and the mother's hands should be clean. Whenever possible children of the tenements should be removed to the country during the summer. Cholera infantum is a bacterial disease, of course, although the specific organism has probably not yet been isolated. It is, however, believed to be caused by either a modification of the Shiga-Flexner bacillus or by a virulent strain of the Bacillus coli, streptococcus, staphylococcus, or proteus, or both. The practical application of this fact is that the other forms of summer diarrheas have a similar etiological basis, as well as an almost similar symptomatology; and that treatment of the latter conditions, when the line of demarcation between them and the disease under discussion is not well defined, is along similar lines.

**Therapeutic Notes.**

**Treatment of Rheumatic Headache.**—Plique, in Bulletin médical for July 19, 1913, enumerates, after Auerbach, the following differential characteristics of rheumatic headache: Incidence usually in elderly persons, often of the female sex; radiation of the pain from the occiput as starting point; exposure to cold as an etiological factor; constancy of the pain without any interval of complete cessation; unilateral situation of pain rare; absence of vomiting, aura, and almost always, of similar affection in the antecedents. Tender nodes varying in size from a millet seed to a pea may be noticeable under the skin, in the fascie, or in the deeper tissues of the posterior or lateral aspects of the neck, down to the shoulders. And are pathognomonic.

Prophylaxis consists in avoiding exposure to cold, and in particular, refraining from washing the head with cold water; the latter should be replaced by alcohol, and thorough drying should follow. Alcoholic beverages should be abstained from and regular bowel movements procured.

In the treatment of the developed condition, patients expecting drug medication may be given potassium iodide, together with mild sedatives, such as potassium bromide, codeine, antipyrine, and zinc phosphide, during the attacks. Iron, arsenic, and general hygiene are also advisable.

Massage is, however, the most efficient therapeutic procedure, and should be practised for fifteen or twenty minutes daily, and later, as soon as improvement is noticed, on alternate days. Hot fomentations applied to the parts, for an hour or two before the massage, are of marked value. Where the callous areas are large and very hard, an ointment consisting of one part of ichthyl in five parts of hydrated wool fat is useful as a preliminary application, which is further to be rubbed in during the massage.

In severe cases, massage should be performed by the physician himself, the patient's head being meanwhile supported by his or her hands on a table, in order to avoid painful commotion of the head. Effleurage of the neck, from the mastoid to the acromion, should first be practised, with the palms. Then pêtrissage of the skin and muscles should be executed five times, the attempt being made, as it were, to detach the deep muscles from their inferior attachments and seize them between
the fingers. This is followed by more effleuraage, and finally, by rubbing of the small nodosities, each for not more than half a minute, as though one were trying to dissipate them by pressure. General effleuraage terminates the procedure. The patient should then remain quiet for from one half to one hour, preferably in the recumbent posture.

With such treatment improvement, even in grave cases that have necessitated abandonment of the patient’s occupation, is generally secured in two or three weeks, though a complete cure may demand six weeks or more. Radium emanations, particularly inhalation of them in closed chambers, are worth trying in cases that remain partially unrelied.

How to Administer Codliver Oil in the Form of a Jelly.—Mouchon, in Paris médical for July 12, 1913, is credited with the following formula for the above mentioned purpose:

1. Gelatini puri, 35 gr. (16 grammes);
2. Aque, 60 gr. (250 grammes);
3. Olei morrhuae, 33 gr. (125 grammes);
4. Olei cinnamoni (vel coriandi, etc.), q. s.

Fiat secundum artem.

The gelatin should first be dissolved in the water, the latter having been previously heated to boiling. The syrup, oil, and aromatic essence are then to be added, the receptacle placed in cold water, and the mixture beaten for five minutes and then allowed to solidify.

Treatment of Bronchitis in Infancy and Childhood.—G. A. Sutherland is credited, in Pediatrîcs for March, 1913, with a description of the management of these cases, essentially as follows: The patient should be kept in bed in the acute pyrexial stage, and placed on a restricted fluid diet. Warm demulcent drinks may be given freely. If the cough is dry and irritating steam inhalations, for fifteen minutes at a time every hour or two, may give great relief, but if there is a free and overabundant secretion of mucus, this measure is contraindicated.

If there is dyspnea from bronchial spasm hot fomentations to the chest, front, and back, with, perhaps, a drachm (4 c. c.) of turpentine added, will often give relief. If plain fomentations are used, they may be applied continuously for an hour and then intermitted. In many mild cases it is sufficient to apply to the chest twice daily a stimulating liniment such as the following:

1. Limimenti terebinthinae acieeti (N. F.), 33 gr. (12 c. c.);
2. Limimenti belladonneae, 33 gr. (4 c. c.);
3. Olei linii, 33 gr. (8 c. c.).

M. It. linimentum.

At the onset of the attack three grains (0.13 grammes) of powdered rhubarb and two grains (0.06 grammes) each of gray powder and magnesium carbonate should be given at night, and followed in the morning by one drachm (4 grammes) of sodium or magnesium sulphate. A simple febrifuge mixture such as the following may be ordered:

1. Liquors ammonii acetatis, 3 xvi (1.0 grammes);
2. Potassii citratis, 3 xvi (0.3 grammes);
3. Tinctura aurantii dulcis, 3 xvi (0.3 grammes);
4. Aque camphorae, q. s. ad, 3 xvi (40 grammes).

Fiat mistura.

Most cough mixtures upset the digestion. In the early stage, when there is dry catarrh of the tubes, two grains (0.13 grammes) of potassium iodide and one half to one grain (0.03 to 0.06 grammes) of ammonium carbonate may be added to the mixture, or given separately, as long as necessary. When the secretion is overabundant, a diminution may be effected by the following:

- Tinctura belladonnae ferment., 3 xiv (0.6 c. c.);
- Aedii nitrohydrochlorici diluti, 3 xii (0.2 c. c.);
- Glycerini, 3 x (0.6 c. c.);
- Infusi gentianae compositi (N. F.), 3 x (1.4 c. c.).

M. Sig.: One teaspoonful every four or six hours.

When there is persistent cough one should examine the nasopharynx and throat for signs of irritation, which may be relieved by a nasal lotion or a simple throat lozenge. If rest at night is disturbed, from five to ten drops of paregoric may be given occasionally to procure relief.

In the stage of convalescence a combination of codliver oil and hypophosphites gives good results in restoring a healthy condition of the bronchial tubes.

Treatment of Erysipelas.—Cavazzani, in Paris médical for May 10, 1913, is credited with the following combination to be applied in erysipelas:

1. Camphora, 1 gr. (1.0 grammes);
2. Aedii tannici, 1 gr. (1.0 grammes);
3. Glycerini, 1 gr. (1.0 grammes).

Solve.

The preparation should be painted over the involved area, and slightly beyond it, every three hours.

Treatment of Tuberculosis.—Lereboullet, in the recently issued Thérapeutique des maladies infectieuses, favorably mentions the so-called "recalciﬁcation" treatment, first advocated by Ferrier, Sergent, and Rénon. In this form of treatment, the following three measures are to be instituted:

1. The ingestion of inorganic or organic acids is to be limited in so far as is possible, though some chlorides are to be allowed.
2. Calcium is to be administered in some such form as this (Sergent):
   1. Calcii carbonatis, 1 gr. (0.3 grammes);
   2. Calcii phosphatis, 1 gr. (0.3 grammes);
   3. Sodii chloridi, 1 gr. (0.15 grammes);
   4. Magnesii oxidi, 1 gr. (0.6 grammes).

M. et pone in cachetam No. i. Sig.: One cachet twice daily with meals.

3. Fermentative processes in the stomach are to be overcome. Three quarters of an hour before each meal a glassful of some mineral water rich in bicarbonates, preferably of calcium, is to be taken.

The treatment may be further reinforced by the administration of calcium chloride in dilute solution, and by the addition to the cachets, already referred to, of from five to eight drops of a 1 in 1,000 epinephrin solution or an appropriate dose of dried adrenal substance.

Where the diet measures instituted in connection with recalcification are not made too severe, this method gives distinctly good results in tuberculoscs and is worthy of being frequently recommended. In elderly tuberculous patients, however, who are often subject to arterial hypertension and in whom the ingestion of large amounts of calcium salts might be prejudicial, some caution is necessary in advising this form of treatment.
THE PATHOGENIC ORGANISM OF RABIES.

The pathogenic organism of rabies, the source of toxins or endotoxins found by Pasteur in abundant quantities in the nerve centres, has been sought with much zeal by many investigators, including Rivolta, Foll, Ferran, and Memmo, the latter having substantiated his statement by reproducing the disease by means of his microorganism, in dogs, rodents, and birds. These statements have not, however, owing to their inability to meet all requirements, earned the acceptance of investigators and the question as a whole still belongs to the domain of conjecture.

Recent labors by Doctor Noguchi at the Rockefeller Institute seem to afford greater hope of a successful issue, though it is impossible at the present time to foretell the importance of the discovery in the therapeutics of the disease. In the course of studies initiated last year, this accomplished investigator obtained fifty cultures of the cerebrospinal system of infected guineapigs, rabbits, and dogs by employing the culture methods resorted to for the relapsing fever spirochetes. Extremely minute polymorphic granules ranging in size from one micron to twelve micra were found which reappeared in new cultures in the course of numerous transplantations. Besides these minute bodies, Noguchi observed round or oval nuclear bodies showing a highly refractive, distinct membrane different from that of the former though occurring in the same cultures. These oval bodies appeared suddenly and lasted four or five days, disappearing concomitantly with an increase of the granular bodies. They were observed in cultures of fixed and passage virus which had produced hydrophobia, though in two instances the negri bodies could only be demonstrated with difficulty either in films or sections. They multiplied by fission or budding, but exhibited the characteristics of protozoa rather than of bacteria.

Noguchi produced rabies in guineapigs, rabbits, and dogs by inoculating these animals with cultures containing the nuclear bodies. The symptoms were typical, while film preparations from the brains of the animals always contained the nuclear bodies in large numbers. On the whole, the results obtained exceeded by far those previously attained and fully warrant the belief that at least a probable clue to the nature of the virus of rabies has been discovered.

THE THERAPEUTIC USE OF PRISMS.

In the July number of the Annals of Ophthalmology, Wendell Reber presents a strong argument in favor of a conservative treatment of cases of imbalance of the ocular muscles, rather than of submitting such patients at once to an operation. We believe that in many cases of muscular imbalance we are dealing with ocular symptoms of an unbalanced nerve action, rather than with demonstrable lesions of the muscular or nervous system, and that every condition of the organism that may disturb the nervous equilibrium, whether in the eye or not, should be taken into account in deciding upon the treatment of any individual case, so we agree with him that "there is no department of ophthalmic science which more requires that the surgeon shall be not only a thoroughgoing refractionist and oculomycologist, but also something of a neurologist and an allwise general practitioner."

Among 7,000 consecutive patients he found 1,276 who had muscular imbalance. In 267 of these the symptoms were dispelled by the correction of the refraction alone and needed no treatment directed toward the muscles. The remaining 1,008 cases of exophoria, esophoria, and hyperphoria were treated with prisms in one of two ways; either by using them for exercise at stated intervals, or by wearing them incorporated with the glasses in the position of rest. Prism exercises gave good results in exophoria in 130 cases out of a possible 190, nearly seventy per cent.; poor results in forty-six, twenty-four per cent, and unknown in fourteen. In esophoria they gave good results in fourteen out of a possible twenty-eight, fifty per cent; poor in

NEW YORK, SATURDAY, SEPTEMBER 20, 1913.
eight; unknown in six. In hyperphoria the results were generally poor, so these exercises were tried in only fourteen cases. When the prisms were incorporated with the glasses the results were much better; twenty-two good out of a possible twenty-four of esophoria, 193 good out of a possible 250 of exophoria in which the glasses were worn constantly, 135 good out of 160 of exophoria in which the glasses were used for reading only, and 297 good in 336 cases of hyperphoria. The known failures from this second mode of treatment with prisms amounted to about ten per cent.

These figures speak strongly against submitting any patient to an operation for an imbalance of the ocular muscles until this conservative treatment with prisms has been thoroughly tried. The textbooks agree in recommending this treatment, but it is mentioned less often in current literature than the operative, possibly because the brilliant possibilities of an operation always form more interesting reading than the humdrum actualities of everyday practice.

THE MEDICAL INSPECTION OF INFANTS AND CHILDREN UNDER SCHOOL AGE.

Among the many valuable papers read at the English speaking conference on infant mortality held on August 4th and 5th, in London, that by Dr. David Forsyth is especially worthy of earnest consideration. He points out that the widespread physical deterioration that overtakes children during the first four or five years of life is only now beginning to receive the attention its importance deserves. This fact has been clearly established by the medical inspection of elementary school children, the majority of whom prove to be physically unsound, most of their defects, moreover, being preventable. The age between infancy and school needs to be medically supervised, together with facilities for remedial treatment, extending over the whole of the first lustrum. In Great Britain and in America too little or nothing has been done toward the solution of the problem. In Great Britain, and to a lesser extent in America, much has been effected in the way of antenatal hygiene and in the care of the child during the first year of life, with a consequent remarkable reduction of infant mortality. But, as Forsyth shows, the results of medical inspection have already clearly demonstrated the fact that the physical defects of the future school entrants do not exhibit themselves until the second year at earliest and that therefore preventive measures limited to the first year are unlikely to have much influence in warding off these later troubles.

The scheme followed in the city of Westminster by the Westminster Health Society is outlined by Forsyth, the essence of which is to keep every child under medical supervision from the time of its birth up to the end of its fifth year and then to hand it over sound and healthy to the school authorities, together with the medical record of the material facts in its life for the information of the school doctor. In America, owing to better conditions of living, young children are not so liable to physical defects as in Great Britain and in Europe generally. On the other hand, the population is becoming more and more urban, the quality of the immigrants is not as good as formerly, either as regards physique or education, and the infant mortality in many cities is far too high. Though the question of conserving the lives and health of young children may not be now so pressing as in Europe, it is yet an important one and is becoming more insistent every day. It will be wise to grapple with the problem in time and to take warning by the bitter experience of Europe in this respect. Consequently, Doctor Forsyth's paper is timely both as regards America and Great Britain.

THE SANITARY RESULTS OF AMERICAN OCCUPANCY OF THE PHILIPPINES.

The possession of the Philippines is scarcely to be regarded as an unmixed blessing to this country; yet, whatever may be one's opinion as to the propriety or desirability of long continued or permanent possession, it must now be acknowledged by all that as regards sanitation and health, as well as in various other respects, their occupancy by the United States, despite some individual hardships, has been of vast benefit in general to the people of those islands. Moreover, it is stated on reliable authority that, although the sanitary work in the Philippines, equal to that in the Canal Zone, has attracted comparatively little attention, the great results accomplished there, among a population of eight millions occupying an area of one hundred thousand square miles, have practically cost the United States nothing; on the other hand, in the Canal Zone, with an area of only three hundred and eighty square miles and a population of but seventy thousand, the work has cost the government nearly fifteen million dollars.

Some of the happy results following American occupancy were set forth by Colonel L. Mervin Maus, Medical Corps, United States Army, in a most interesting paper read at the last meeting of the Medical Association of the Greater City of New York, in which he described the special achievements of the civil government in the Philippines, which, he said, might well be compared to the admirable work of the army medical board in the suppression of yellow fever in Cuba. When the American troops entered the city of Manila
they found the existing sanitary conditions about like those of the European towns during the middle ages. There was practically no board of health for the Philippine Islands, and but few hospitals, and while there were no vital statistic records, there was reason to believe that no less than eighty per cent. of the children died in infancy from malnutrition, gastrointestinal disease, and convulsions. The people were also illiterate, but few of the natives being able to read or write, and their general condition might aptly be compared to that of our semi-civilized Indians in Arizona and New Mexico. At the end of the first year of its existence the Insular board of health, which was organized in 1901, had succeeded in reducing the death rate in Manila one half, and through its efforts the sanitary conditions there and, indeed, throughout the archipelago, were revolutionized. Among the acts of the board were the creation of laws regulating the practice of medicine, midwifery, dentistry, veterinary surgery, and embalming, and undertaking, and of laws providing for compulsory vaccination, the segregation of lepers, and the organization of provincial health boards.

One of the greatest menaces to health was small-pox, which prevailed in a virulent form throughout the islands; but as the result of the enforcement of the law requiring compulsory vaccination the disease was eliminated. In 1901 there occurred a serious epidemic of bubonic plague in the city of Manila, and this was completely overcome by the universal and systematic extermination of rodents. In 1892 Asiatic cholera broke out in Manila and rapidly spread throughout the archipelago. On account of the ignorance and superstition of the natives it was a difficult situation to handle, but the disease was held in check after a time, and eventually eradicated, though this required some years of effort on the part of the authorities. As to the segregation of the lepers, who are numerous, it was decided, after mature deliberation, to colonize them on a single island. This was selected with care, and it was equipped for the desired purpose, with suitable quarters, hospitals, schools, churches, etc. The colony has now been in operation for some years, and it is believed that within the next generation leprosy will disappear from the islands.

THE CAUSES OF ANEMIA IN MALARIA.

Among the most interesting chapters of recent work on malaria is that concerned with the origin of the blood changes typical of this disease. Besides the destruction of red corpuscles through direct development of the malarial plasmodia in them, there have been suggested several accessory causes of the anemia in this affection, prominent among which is that of a toxin prejudicial to the cells, circulating in the blood. Recently Wade H. Brown (Journal of Experimental Medicine, July, 1913) has presented an account of researches which lead him to regard the pigment hematin, set free from hemoglobin by the malarial parasite, as an active factor in the production of many, if not all, of the important blood changes observed in the various forms of the disease. Injection of only ten to twenty milligrammes of hematin (to the kilogramme of animal) into rabbits on several successive days was found to produce a well marked anemia, consisting both of reduction in the number of red cells and of the presence of immature cells. The mechanism of this destruction of red cells could not be definitely made out; some degree of hemolysis was often noted, but microscopic study of the tissues showed that red cells were also killed without disintegration, numbers of them being found included within phagocytes.

In addition to its effects on the red cells, hematin was also found by Brown to induce changes in the leucocytes, platelets, and coagulation time. The first were usually increased in number, as in the pernicious forms of malaria, and there was always a high percentage of large mononuclear cells—a characteristic feature of malarial blood. The effect of a single injection resembled the cycle of changes occurring in the leucocytes at the time of the malarial paroxysm. The platelets were found to be markedly reduced in number by hematin, and ultimately a prolongation of the coagulation time and the bleeding time took place. The resulting tendency to hemorrhage has its counterpart in the well recognized class of hemorrhagic cases of pernicious malaria. Thus, so numerous are the points of resemblance between the effects of hematin and those of malaria on the blood that a partial causal relationship of the former to the latter appears, to say the least, probable.

STUDIES OF SYPHILIS.

Studies of Syphilis is the title of the third bulletin, June, 1913, published from the office of the surgeon general, the issue being made possible by an appropriation of a small sum for the year 1913 for publication of bulletins for the instruction of medical officers. The present pamphlet is such a worthy contribution to our science that it is hoped that this appropriation will be continued from year to year in the future. If such would be the case, the surgeon general would be in a position to publish these bulletins quarterly. The present issue contains eight essays contributed by Captain Henry J. Nichols and Captain Charles F. Craig, both attendees at the Army Medical School under the command of Colonel Charles Richard.
Obituary.

THEODORE SCHAEPKENS VAN RIEMPST, M.D.,
of New York.

Doctor van Riempst died suddenly on August 21, 1913, at Saranac Lake, N. Y. Educated at the University of Louvain, he received his medical degree at the University of Ghent, Belgium in 1900. Following an internship of a year and a half at the Stavienberg Hospital in Antwerp, he was appointed surgeon to the Red Star Line. When he resigned in 1907 he was ranking surgeon of the fleet. Coming to New York he specialized in genitourinary surgery and, receiving an appointment in 1910, as assistant genitourinary surgeon to the Massachusetts General Hospital, he went to Boston. After a severe attack of typhoid fever and a prolonged convalescence, he returned to New York, where he had since practised.

News Items.

**Typhoid Fever in St. Louis.**—During the month of August, 1913, there were reported to the Department of Health 172 cases of typhoid fever, and during the first five days of September 72 cases, making a total of 244 cases reported from August 1st to September 6th.

**Meetings of Medical Societies to Be Held in Philadelphia during the Coming Week.**—Tuesday, September 22d, St. Mary's Hospital Clinical Society; Thursday, September 25th, Germantown Branch of the County Society; Friday, September 26th, General Medical Club; Northern Medical Association; Board of Directors of the Medical Club. The Medical Society of the State of Pennsylvania will be held in Philadelphia, September 22d to 25th.

**Cholera.**—According to reports received in Washington, D. C., by the United States Public Health Service during the week ending September 12th, cholera is spreading in Hungary, Rumania, and Turkey in Europe, and press despatches state that the disease is also spreading in Russia. In Rumania up to August 14th, thirty-seven cases in eleven localities, with sixteen deaths, were reported, and on August 21st, forty fatal cases in fourteen other localities were reported.

**To Study Pellagra in the West Indies.**—Dr. Louis Sambon, of the London School of Tropical Medicine, accompanied by Captain Joseph P. Sifer, of the Medical Corps of the United States Army, a member of the Thompson-McPadden Pellagra Commission, sailed a few days ago for the West Indies for the purpose of studying pellagra and other tropical diseases. It is said that plans are being made for an international congress on pellagra to be held in Washington next year.

**Pellagra.**—During the week ending August 23d, one death from pellagra was reported in New Orleans, one in San Francisco, and fourteen cases of the disease in Providence, R. I. Surgeon P. M. Carrington, of the United States Public Health Service, reported two cases in St. Louis, Mo., recently, and five fatal cases previously, making a total of seven cases of the disease since January 1st. In the Eastern Washington City Hospital for the Insane, in Spokane County, Wash., two cases of pellagra have been reported recently.

**New Hampshire Surgeons' Club.**—The autumn meeting of this organization was held at the New Castle-by-the-Sea, on Thursday, September 4th, under the presidency of Dr. T. W. Luce, of Portsmouth. There was a good attendance and an excellent programme was presented, which included addresses by Doctor Luce, Dr. Farrar C. Colh, of Boston, Mass., and Dr. A. P. Leighton, of Portland, Me. Dr. Frank E. Kittredge, of Nashua, was elected president of the club, and Dr. E. H. Carlton, of Hanover, vice-president. The proceedings were brought to a close by a banquet, Dr. H. L. Smith, of Nashua, acting as toastmaster.

Flushing's New Hospital Opened. In Flushing, N. Y., on the afternoon of Wednesday, September 10th, the new $100,000 hospital was formally opened, and as soon as the building has been equipped, most of the patients in the old building will be moved into it. The money for the new hospital was raised a year ago last June in a twelve day campaign. Four stories have been completed, but a fifth is to be added later, which will necessitate an additional outlay of about $6,000.

**Changes at the Army Medical School.**—Many changes at the Army Medical School are involved in orders issued by the War Department on September 9th. Colonel Wallace McIvor of Major Charles R. Foringer, relinquished from further duties. Lieutenant Colonel Champe C. McCulloch, Jr., is assigned to duty as professor of military and tropical medicine; Lieutenant Colonel James D. Glennan, as professor of medical department administration; Major Eugene R. Whitmore, as professor of bacteriology, pathology, and clinical diagnosis, and Captain Edward M. Talbott, as assistant professor of ophthalmology.

The Convalescent Service of St. John's Guild.—On Monday, September 15th, with the opening of the new buildings of the St. John's Guild for convalescents on Roosevelt Island, St. John's Guild inaugurated its convalescent service for the fall and winter terms. Heretofore the work of the guild has been a summer charity exclusively, caring for sick children of the poor and their mothers. To this has been added the fall and winter care of convalescents. Four wards will be used, one for cardiac, one for orthopedic, one for maternity, and one for general cases. The new hospital, which consists of two stories of pavilions, is facing at the front in all cases, whether medical or surgical. Admission to the hospital is gained by a card, signed by the physician under whose care the patient has been, and endorsed by one of the physicians of the Seaside Hospital. The office of the gymnasium is at 103 Park Avenue.

**Distribution of Antitoxine Free of Charge in Manhattan.**—It is the firm conviction and belief of the Department of Health that, if every case of diphtheria in New York city received five thousand units of antitoxine on the first day of the disease, the number of deaths from this cause—now entirely too high—would be markedly diminished. To further this end the Department of Health of the City of New York recently announced that, beginning September 1, 1913, it would, whenever necessary, begin a round of at least two hours of antitoxine, free of charge, to any address in Manhattan, antitoxine for the treatment of diphtheria, provided the request was made to the Department of Health at 149 Centre Street, and the person receiving the antitoxine sign a receipt therefor. (Obtaining a statement (the antitoxine was paid for by the philanthropist Dr. Robert F. Smith of New York City, by which is meant that the amount of money that he contributed was not paid for by the city) was unable to pay for it. This offer is for a limited period only. If physicians avail themselves of it in sufficient numbers, the procedure will be extended to all boroughs and made permanent. The antitoxine will be furnished in syringe containers, ready for immediate use, the empty or unused syringes being collected by the Department of Health the following day.

**A Course in Tropical Diseases at Harvard University.**—The Harvard Graduate School of Medicine announces that the systematic course of lectures, inaugurated at the school on November 1st, and will last six months. It will be open to graduates from all recognized medical schools, and is intended to provide adequate preparation to those physicians who intend to practice where tropical diseases may exist. The course is under the direction of Dr. Richard P. Strong, who was at one time chief of the biological laboratories of the Bureau of Science of the government of the Philippine Islands, and was recently appointed physician at the Boston Dispensary. Dr. Harold C. Ernst, professor of bacteriology in the Harvard Medical School, Dr. Theoald Smith, professor of comparative pathology, and Dr. Milton J. Rosenau, professor of hygiene and preventive medicine, will constitute an advisory board, and, with other professors, both from the medical school and other departments of the university, will participate in the instruction. A detailed announcement of the complete course will be issued later and may be obtained by applying to the dean of the Graduate School of Medicine, Harvard University.
Michigan State Medical Society.—Nearly four hundred delegates attended the forty-eighth annual meeting of the Michigan State Medical Society, held in Flint on Thursday and Friday, September 4th and 5th, under the presidency of Dr. W. H. Sawyer, of Hillsdale. This is the largest number on record, with but one exception. Dr. Guy L. Kiever, of Detroit, was named as president by a unanimous vote. In a short speech before the convention, Doctor Kiever stated how favorable to public health the early commencement of antiscorbutic policy tending toward the improvement of the health of the State. Other officers chosen were: First vice-president, Dr. H. E. Randall, of Flint; second vice-president, Dr. O. E. Taylor, of Jackson; third vice-president, Dr. H. A. Spencer, of Grand Rapids; members of the council, Dr. A. E. Burleson, of Jackson, Dr. A. L. Seeley, of Mayville, and Dr. R. S. Buckland, of Baraga. Next year’s meeting will be held in Lansing.

Personal.—Dr. Ralph G. Springer has resigned as supervising medical inspector of the public schools in Philadelphia, pressure of duties in connection with his practice being assigned as the reason. His successor has not yet been appointed.

The U.S. surgeon, medical director in the United States Navy, retired, has been appointed medical director of Jefferson Hospital, Philadelphia, succeeding Dr. E. H. Funk.

Dr. L. L. Naecher, of New York, professor of geriatrics in the Boston College of Physicians and Surgeons, delivered the address at the opening of the thirty-fourth session of that institution on Wednesday, September 17th, his subject being The Medical Care of the Aged.

Golden medallions were awarded by Rebman Company and Messrs. Fairchild Brothers & Foster, of New York, for their exhibits at the Seventeenth International Congress of Medicine, held in London last month, to the former for medical publications, and to the latter for their physiological pharmaceutical preparations.

New Regulations Regarding the Shipment of Bodies Dead from Infectious Diseases.—At a meeting of the Department of Health of the City of New York, held on July 30, 1913, the duties of undertakers in cases in which death was the result of infectious diseases were discussed, and certain rules relating to the shipment by rail or boat of bodies thus infected were formulated. It is desired again to call attention to these rules, which differ to some extent from those which have previously been operative. They are as follows:

In deaths from infectious diseases where the remains are to be shipped by rail or boat:

(1) The inspector of the division of infectious diseases shall determine who may accompany the remains to the place of interment or cremation.

(2) The undertaker, in addition to complying with rules heretofore specified, shall file with the Department of Health a certificate of the death caused by infectious disease. The rules of the State Department of Health have been complied with as to the preparation, disinfection, embalming, and enclosure of the remains, and to the certificate of the undertaker as to the method of disposal. Prior to the use of the rigid rules under which the body is being shipped or transported, and he shall notify in the name of the Department of Health of New York city, by telegram and before shipment of the remains, the health officer at point of destination, advising the date and time upon which the remains may be expected.

Kentucky State Medical Association.—The sixty-third annual meeting of this association was held in Bowling Green on Tuesday, Wednesday, and Thursday, September 23d, 24th, and 25th under the presidency of Dr. W. C. Roberts, of Louisville. There were about four hundred delegates in attendance, and the meeting was in all respects one of the most interesting in the history of the organization. The most important feature of the council session was the election of officers, which resulted as follows: Dr. J. W. Ellis, of Masonville, president; Dr. A. T. McCormack, of Bowling Green, reelected secretary; Dr. W. B. McCure, of Lexington, reelected treasurer; Dr. H. H. McWright, of Richmond, second vice-president; Dr. J. C. Dowell, of Cynthia, second vice-president; Dr. J. B. Kinnaird, of Lancaster, third vice-president; Dr. D. S. Wilson, of Louisville, counselor. Fifth District: Dr. E. Rau, of Bowling Green, reelected chairman of the medical society. Sixth District: Dr. J. R. Wieck, of Cincinnati, chairman. Eighth District: Dr. W. W. Richmond, of Clinton, reelected delegate to the American Medical Association. Dr. W. P. Poole, of Henderson, orator in medicine; Dr. A. D. Whipple, of Louisville, orator in surgery. Newport was selected as the meeting place for 1914.

Alcohol in Infectious Diseases.—C. A. Ewald believes that the freedom of Europeans from becoming infected with the pest. prevalent in India, was rather due to the general hygienic mode of life of the Europeans than to their consumption of alcohol. With regard to infective diseases of the tropics, it is the expressed opinion of all observers, that alcohol has a decidedly deleterious effect, in that it lowers the resistive power of the organism, and increases the susceptibility to infection. All authorities agree that children should be given as little alcohol as possible. In all nervous conditions, epilepsy, gout, and in chronic diseases of the heart, kidney, and liver, alcohol should be prescribed. Rosenfeld drew attention to the fact that digitalis was borne longer in heart disease by those who had abstained from alcohol; an observation which the author could substantiate. The writer observed that in continuous vomiting after chloroform narcosis and in convalescence from typhoid alcohol may at times be of use. According to Collin, after refusal of food for several days, and in cases of continuous vomiting, its careful administration may assist in sustaining the patient. A direct indication for its use is found in diabetes, as it decreases acidity.

Diuresis.—L. Hess reviews some new methods of diet (the salt free diet (von Noorden, Strauss, Widal), and the Karell cure). Von Noorden advocates a decreased consumption of fluids, the aim of which is to save work for the heart and kidneys. This is directly opposed to former methods of flushing the kidneys with large quantities of fluids. In treating chronic nephritis von Noorden limits the quantity of fluids to from 1,500 to 2,000 c.c. during the day, and permits only occasionally, or at longer intervals, a day for a larger intake of fluids. This is a prophylactic where there is a tendency to edema, as in chronic parenchymatous nephritis, in all cardiac weaknesses resulting from fatty degeneration, and in sclerosis of the coronary vessels. The second dietary method—the salt free diet—is only indicated where a renal disturbance results from an inadequate elimination of sodium chloride resulting in edema. Should the dropsy be the result of other causes, as poor circulation from weakened heart action, or from primary insufficient excretion of water by the kidneys, the salt free diet is of no avail. Foods most free from salt are: Eggs, sweet butter, fruit, vegetables, salads, and asparagus; cereals, fresh water fish, and the different varieties of white meats. The beverages advised are water, tea, coffee, and grape juice. Bread should be baked without salt, and have other flavoring substituted, as kümmel (caraway seed) or mohn (poppy seed). Strauss recommends eggs in the form of omelette with jelly and tomato stew. Salt should be omitted in the preparation of all vegetables; in its place thyme, laurel leaves, sweet marjoram, and at times parsley may be used. Milk diet results in lowered nutrition, and contains too large a proportion of sodium chloride. The Karell cure has given
good results where renal disturbances complicated with arteriosclerosis and myocarditic processes are the cause of dropsy. For from five to seven days the patient receives a diet of boiled milk 200 c.c. four times daily, at 8, 12, 4, and 8 o'clock, the patient remaining in bed during the treatment; for the following two to six days, one egg only is added at 10 a.m., later also some zwieback. Twelve days after the beginning of the cure, full diet is gradually allowed, and in the following two to four weeks the total amount of fluids given should not exceed 200 c.c. daily. By strict adherence to these rules active diuresis is attained in about three days without the use of medicines. Subjective relief of cardiac oppression follows and this in patients with whom, in the beginning, diuretics had failed.

August 10, 1912.

Pathology and Therapy of Renal Calculus.—W. Karo observes that in view of our limited knowledge of metabolism, we do not yet know what foodstuffs cause the precipitation of oxalates, phosphates, xanthin, and cystin, all of which may give rise to stone formation. Rosenbach has shown, by experiments on dogs, that a healthy kidney has the power of ridding itself of concretions. The appearance of acute phenomena, caused by the presence of stone, can only be met by symptomatic treatment. For pain, hot applications, as hot sand or poultices, applied to the region of the kidneys; hot baths also prove grateful. Posture may sometimes prove beneficial. Massage sometimes causes the calculus to change its position and in this manner the pain is relieved. When the pain becomes intolerable or if there is long continued colic, a hypodermic injection of morphine or a suppository of 0.008 gramme of heroin with 0.25 gramme pyramidon will relieve. The patient should drink freely of milk, tea, and any of the mineral waters suited to the character of the concretions. An internal urinary antiseptic is given as a prophylactic against secondary infection for the trauma caused by renal colic. To prevent any recurrence of the attack, a rigid diet, in accordance with the nature of the concretions, is observed and the urine is kept neutral. A mixed diet is given. Very little meat, no thyme, liver, kidney, nor caviar. Give generous portions of vegetables and fruits. To increase the alkalinity of the urine bicarbonate of soda, or perhaps magnesia, 2 grammes, three or four times daily; carbonate of lime is also useful. Table waters should be chosen according to the character of the concretions we wish to combat.

August 17, 1912.

The Significance of Ions as Therapeutic and Climatic Factors.—P. Grabley says that the influence of wind, the vapor content of the air, as well as the atmospheric pressure, have been fairly well investigated; but not so the electric phenomena nor the ion content of the atmosphere. For instance, it has been found that the motion of the wind and not the salt content of the air, is of therapeutic value at the seashore. That an increase of hemoglobin in the blood is made by the low barometric pressure of great altitudes; but what it is that causes many sick, and also many healthy, sensible people, independent of location and climate, to become generally irritable, has not yet been explained.

It is a well known fact that many people experience a feeling of discomfort before a thunder storm, followed by a feeling of wellbeing when the electric tension of the atmosphere was accompanied by precipitation. It was observed that this depended upon the meeting of various components of the atmosphere. Ions originate almost exclusively from radium emanations streaming from the ground into the air. After vapor precipitation, and the production of high water levels, gas forming ions escape from the pores of the earth with difficulty. Therefore there are more ions passing out in dry weather. The quantity of radium emanation depends upon the character of the soil. When eruptive concretions are present in the deeper strata of the soil, and when the soil is very porous, ions stream out abundantly. Great activity and numbers of ions in great altitudes and mountains, as compared with those of the lowlands and seashore, are thus explained. The author believes that treatment in an air space, of large cubic content of negative ions, given for gout, rheumatism, and various nervous diseases, would give the same results as when treated with radium emanations.

August 24, 1912.

The Etiology of Arteriosclerosis and Its Significance in Therapeutics.—M. Herz explains that persons with arteriosclerosis present changes in bloodvessels resulting in certain functional disturbances. These may be divided into three classes: 1. Changes in the cerebral vessels; 2, changes in the coronary vessels of the heart, and in the aorta; 3, changes in the vessels of the kidneys. Among various causes the author lays most stress on the psychic attitude of the patient. With regard to physical work, he notes that people working much with their hands often suffer with sclerosis of those vessels. Farmers who make most use of their legs often develop sclerotic vessels of their legs; but these varieties have no relation to those of the psychic nature, which are rather brought on by sorrow and worry and this cause, though frequent, is hardly referred to in textbooks, though the intimate relation between bloodvessels and mind is well known. For the cerebral neuroasthenic form of arteriosclerosis we give potassium iodide in small doses. For the thorastenocardial character, nitrite of theobromine is indicated. The third group is where the contracted kidney is prominent and possibly only detected by continuous high blood pressure and where no albumin may be found in the urine. Only diet is indicated in this third variety; potassium iodide and theobromine are useless. The author lays stress on prophylaxes: the teaching of which should begin with the children. With regard to the all important psychic treatment, he urges the practitioner to be a spiritual friend to the patient, as well as well as a family friend.

August 31, 1912.

The Present Status of Dietetics in Nephritis.—T. Janowski reviews the dietetics of nephritis as having shown deficiency in variety and as having been prescribed rather too summarily. The selected diet of to-day is more in keeping with individualism. The tolerance of the kidneys must be ascertained. This has proved of service in diabetes. For instance, a patient whose kidneys excrete so-

PITH OF PROGRESSIVE LITERATURE.
dium chloride, may take it in his food as he deems necessary and so with nitrogenous substances. The careful findings in the urine should aid in the selection of the diet. Patients excreting albumin should not be stinted in the albumin content of their diet; but should rather be given sufficient to replace that lost in the excretions. The degree of tolerance for work, on the part of the diseased organ, should be carefully estimated. Pumpkin caused no irritation of the kidneys, and when eaten in sufficient quantity, resulted in diminishing the number of erythrocytes, cylinders, and epithelial cells in the urine; but even more important was the fact that in many patients it was known to increase diuresis.

**ZENTRALBLATT FÜR GYNAKLOGIE.**

*August, 1912.*

The Clinical Importance of Abderhalden’s Serodiagnosis in Pregnancy.—Mayer considers Abderhalden’s reaction to be of great importance in several ways. He believes that it is positive in the very earliest stages of pregnancy and may be therefore of great value in medicolegal cases. As the reaction remains positive for two to three weeks after delivery it likewise may be used to determine whether or not there has been a previous pregnancy. In relation to extraterine pregnancies the reaction is positive only in recent cases, being negative in old hematocoles where there is no longer any functioning tissue. Mayer states that in fifteen cases of eclampsia the test was distinctly less marked than with normal placenta. He also considers that probably the greatest value of Abderhalden’s reaction may be along the lines of investigation of the pathology of the internal secretions, inasmuch as this method enables one to determine the presence, within the blood serum, of foreign substances.

Trachelorrhaphy as Prophylaxis for Cervical Cancer.—Asch believes that at the present time sufficient attention is not paid to the importance of repairing lacerations of the cervix, particularly as they not uncommonly are the locations in which cervical carcinoma develop. Even if so serious a condition does not result the inflammatory process may extend upward giving rise to endometritis, dysmenorrhea, and menorrhagia.

Serodiagnosis of Pregnancy.—Porchownick, after calling attention to certain difficulties encountered in the making of Abderhalden’s reaction, reports several groups of cases in which he employed this method of diagnosis. As a result of his investigations he concludes that the dialysis method of Abderhalden is fairly trustworthy in making a diagnosis of pregnancy at a time when the findings of a gynecological examination are insufficient. He also finds that the reaction will appear for some two weeks after pregnancy. It also is valuable in the diagnosis of extraterine pregnancies, although in general the reaction is not as marked as in normal cases. Sometimes a slight reaction is obtained in patients who are not pregnant but are suffering from fever. This is probably due to the presence of substances resulting from increased cleavage of albumin. This can be differentiated from the true reaction in pregnancy by the fact that the control dialysate will also show color changes.

Partial Retroflexion of a Pregnant Uterus.—Fonyó reports a case in which a diverticulum of the posterior wall of the uterus extended behind the promontory and was adherent to the coccyx. In this portion was situated the placenta.

**PRESSE MÉDICALE.**

*August 16, 1912.*

Investigation of Nitrogenous Metabolism as Reflected in the Urine.—L. Lematte describes a method of separating and estimating volumetrically the urea and ammonia in the urine. It is based upon the fact that when phosphotungstic acid and magnesium chloride in definite proportions are added to urine, all the ammonium salts are precipitated, leaving the urea, which can be estimated by the hypobromite method. Again, if urine be treated with lead subacetate, all nitrogenous compounds except ammonia, urea, and aminoacids will be precipitated. Upon testing such a urine by the hypobromite method, the sum of the ammonia and urea nitrogen can be ascertained.

*August 20, 1912.*

Agglutination of Micrococcus Melitensis.—Martel, Tanon, and Chrétien, discussing the prophylaxis of Malta fever, state that in order to diagnosticate the disease in goats, serum agglutination in dilutions greater than one in 100 must be present. A blood culture, on the other hand, permits of making a diagnosis in all safety. In all cases showing agglutination, raw milk, or cheeses made from the milk of goats that are suspected of, or actually show, melitococcia should be forbidden.

Modified Technic in Application of Thielsch grafts.—P. Hardouin advises waiting, before applying Thielsch grafts, until the surface to be covered shows reddish granulations, bleeding readily, and the discharge has been reduced to a slight serous or seropurulent oozing. A few days before grafting, moist dressings should, if necessary, be applied to soften crusts; a one in 1,000 solution of potassium permanganate is recommended. On the day preceding operation, a dry dressing should be applied. In preparing the surface for the grafts, the entire layer of fleshy granulations should be removed with a curette, until a firm stratum of tissue, with a whitish, fibrous appearance, is exposed. After rubbing this surface with a gauze compress, bleeding can be immediately arrested by placing dry gauze over it. The area from which the grafts are to be taken, usually the thigh, should then be strongly rubbed for three or four minutes with a pledge of gauze saturated with alcohol, until the skin has assumed a reddish color. After allowing the alcohol to evaporate, one next washes the area with warm normal saline solution. In removing the grafts, which should be as thin as possible, the razor should be seecawed tangentially to the skin, and the grafts kept on the blade throughout, i.e., not transferred, as is sometimes done, to a spatula and spread out before application to the open surface. When the latter has been completely covered, the surrounding skin should be carefully cleansed with dry or slightly moistened tampons, and a large compress consisting of six or eight thicknesses of dry gauze bandaged tightly over the
area. No impermeable covering should be used. The gauze should be left on six or seven days. Its removal without injury to the grafts, the use of a spatula for the purpose of separation being sometimes required about the edges, can usually be accomplished easily. Where this is not the case, bathing in salted water for an hour or two will be sufficient to liberate the adherent gauze. A fresh, similar dressing is then to be applied. With this technic, perfect healing is not uncommonly observed when the first dressing is removed, and in any case, the desired result is obtained much more quickly than after the use of impermeable dressings.

REVUE DE MÉDECINE.
August, 1913.

Anastomoses between the Greater and Lesser Circulations.—Charles Trunecek calls attention to the fact that there normally exist in certain situations communications between the vessels of the systemic and pulmonary circulations. Thus the bronchial capillaries and veins open into the pulmonary veins instead of into the veins of the systemic circulation; most of the veins from the walls of the left auricle, and some from the left ventricle, open into the left side of the heart. Besides, there are anastomoses between the mediastinal venous plexus, and diaphragmatic, and esophageal veins, on the one hand, and the pulmonary veins, on the other, as well as between the anterior bronchial veins and the pulmonary veins. These communications between the two systems afford an explanation of the hitherto puzzling fact that the output of blood from the left ventricle is somewhat greater than from the right; of the early congestion of the bronchi and precordial discomfort observed in mitral insufficiency, even where the valvular defect is still compensated for; of the fact that lung infarcts are always of the hemorrhagic variety, while elsewhere anemic; and of the excess of hypertrophy of the left ventricle over the right almost constantly observed in plethora. This anatomical condition, moreover, permits of the passage of certain bodies contained in large amount in the venous blood into the arterial blood, in particular carbon dioxide, which in the arterial blood regulates and strengthens the respiratory and cardiac movements and prevents acapnia at great altitudes. Where, owing to various pathological states of the heart, the normal ratio in the outputs of the left and right ventricles is not preserved, the communications between the systemic and pulmonary circulations described permit of readjustment of the blood flow, thus relieving an otherwise unavoidably serious condition.

Asthenic Form of General Paralysis.—R. Benoît and H. Cier assert that nearly all cases of general paralysis that are depressed, neurasthenic, hypochondriac, and melancholic, are in reality asthenic, i.e., that physical weakness accompanies and even underlies the mental weakness in this stage. This is followed, as in two cases reported by the authors, by a period of hyperasthenia or mania, with mental and motor excitement, euphoria, ideas of grandeur and satisfaction, etc. The diagnosis between true neurasthenia and the asthenia of beginning general paralysis rests, above all, upon examination of the mental state, viz., for the disorders of judgment and emotion characteristic of early paresis.

The Psychasthenic Diathesis.—S. Lubetzki, from a study of some thirty psychasthenic patients for a period of several years, is impressed with the fact that there exists a species of diathesis or psychasthenic soil, the subjects of which are predisposed to mental eccentricities, doubts, tics, phobias, anxieties, etc., which may coexist, appear, or disappear at different times in the same individual. Sensitiveness, a tendency to the absolute abstract rather than the concrete, and abulia, are the three essential stigmata of the psychasthenic mental state. The toxic effects of the tubercle bacillus, generally in incipient cases, may be responsible for psychasthenia, while influenza often aggravates a preexisting psychasthenic state. The prophylaxis of psychasthenia consists in toning up the system, ordering special attention to the physical rather than the mental side of life, hydrotherapy, and the choice, for the maturing individual, of a profession which will not involve too great a drain on the nervous system. In the curative treatment of psychasthenia, rest, injections of lecithin or oil in increasing amounts, and a substantial diet, with the omission of fermented beverages and of meat in the evening, are essentials. These measures will facilitate the subsequent psychic treatment, in which an attempt should be made to strengthen the patient’s will, lead him to make firm resolutions, and then to overcome through logical discussion of the facts, his systematized fears.

Hematuria in the Course of Typhoid Fever Treated with Hexamethylenamine.—J. Belkowski gave forty typhoid patients hexamethylenamine in doses of 0.5 or 0.6 gramme three or four times daily. Hematuria appeared in four instances, and in one patient death followed. At autopsy the bladder was found the seat of marked desquamation and bloody ecchymoses, and the intestines of numerous ulcers, one of which had yielded, the peritoneum exhibiting a grayish exudate. In the remaining patients of the series there was neither perforation, intestinal hemorrhage, nor relapse. While hexamethylenamine cannot be considered a specific remedy in typhoid, the generally favorable results obtained from its use invite further trial.

BRITISH MEDICAL JOURNAL.
August 30, 1913.

Treatment of Congenital Syphilis by Salvarsan.—J. W. Simpson and Lewis Thatcher have had an experience of forty cases in children ranging in age from one month to eleven years. Their success has been noteworthy and they believe that two factors alone go far to account for it. 1. The use of a suitable dose. This should be 0.01 gramme for every kilogramme (2½ lb.) of body weight. 2. An improved method of injection, which consists in cutting down upon the external jugular vein and inserting a cannula just as in transfusion. This is the method of election in children under one year of age, and in many cases has to be resorted to in those up to three or four years old. Attention is drawn to the undesirability of drawing blood from a small infant for the Wassermann test as this tends to reduce materially the child’s total hemoglobin
and such infants are usually already deficient in this constituent. A Wassermann test of the mother's blood is quite as satisfactory, for it will always be positive if the child is congenitally syphilitic. Practically all of the syphilitic lesions seen in these early congenital cases responded very promptly to the use of salvarsan, only seven infants of the total of forty died, and in no instance was there a truly severe reaction to the injection. In comparison with mercury, salvarsan gives much better results, particularly in the more severe cases. It is always advisable, however, to carry on treatment with mercury and iodide after the use of salvarsan.

**Panniculitis.**—D. Durward Brown employs this term to mean one of the types of fibrosis of other authors—the form involving the subcutaneous tissues—or the disease sometimes known as Dercum's disease. The affection is very painful, very chronic, and if treated properly and persistently enough yields satisfactory results. Aspirin will undoubtedly relieve the pain temporarily, and the bath treatment of Harrogate does much to alleviate the suffering, but the important feature is properly practised massage. This must be performed with the lightest touch in the beginning, and for a few minutes only. Both the amount of pressure and the length of each treatment are to be increased gradually until a full hour of fairly vigorous massage can be given without any discomfort to the patient. In the experience of Brown most of these patients have a large neurotic element at the bottom of the trouble, and it is partly for this reason that it is so hard to treat them successfully, for few have the patience to persist long enough to be cured. The majority of the cases are in women and are seen in five distinct types, according to Brown: In young women after childbirth; in young women with neuroses; in young women after operations; in women after the menopause; and in women with abnormal thyroids, or some other abnormality of metabolism. The chief symptoms are pain on manipulation, specially with rolling movements, and pain simulating neuritis.

**PRACTITIONER**

*August, 1913.*

**The Septum Nasi and Its Deformities.**—Francis Muecke insists that a certain amount of deviation of the septum is almost always present in adults which demands treatment only under certain conditions. When any surgical treatment is needed a submucous resection is best, except in cases of definite spurs. This operation is indicated when there is undoubted interference with breathing; in cases of troublesome nasal catarrh which cannot be cured by ordinary means; if, after an attack of acute otitis media, there is reason to believe that the lesion was actually due to, or favored by, the deformity; in cases of intractable or constantly recurring aural discharge; in cases of chronic catarrh of the middle ear in its early stages, in which improvement is noticed after inflation, especially if the passage of a catheter is interfered with; in cases of unilateral atrophic rhinitis of the concave side; of pharyngitis, laryngitis, bronchitis, asthma, hay fever, and severe headaches which have resisted all other forms of treatment. The external appearance he finds may be improved by the operation, as ten of the seventy-four patients with whom he has been able to keep in touch volunteered the statement that their noses are now straight. He is convinced that a certain amount of reformation of cartilage takes place. The results were satisfactory in all of the seventy-four cases.

**Erythema Nodosum.**—A. Hope Gosse analyses 100 cases of erythema nodosum, which he believes to be an infective disease of separate entity. A specific germ has not yet been discovered. It is a disease of childhood, occurring about equally in males and females, before the age of twenty, but after that age almost wholly in females. It is more prevalent in spring, summer and early autumn. The cases are as a rule sporadic, but two or three members of the same family have been affected at the same time. Three cases described in one family suggest a period of about a fortnight from infection to the appearance of the rash. The onset of symptoms is frequently marked by an attack of tonsilitis; there may have been previously repeated sore throats, or, rarely, the tonsilitis may have been coincident with that of another disease. The tonsilitis may subside, and for a few days symptoms may be entirely absent; then the general infection is marked by a fairly constant train of symptoms. The onset may be sudden, with shivering or even a chill; more often it is insidious, and there are headache, vomiting, and anorexia. Occasionally no symptoms precede the rash. In the severe cases pain in the back is very frequent, and joint pains, and even effusion, may occur in the knees, ankles, or wrists. There may be conjunctivitis, and occasionally a phlyctenule. There is some pyrexia in the prodromal period, and sweating is often profuse. These symptoms may persist for any length of time up to about a fortnight, before the characteristic nodes appear. They are always present on the legs, frequently on the forearms, sometimes on the thighs, and arms, and even on the face and trunk. On the limbs it has a predilection for the extensor surfaces, and is usually bilateral. The nodes vary much in size. Bright red at first, they are usually tender and may become progressively more so during the first few days. As a rule they are not painful when the patient is in bed, but often become so when he sits up with his legs dependent. As they fade they pass through all the changes of color of a severe bruise. They fade in from a few days to three or four weeks. Frequently they appear in a succession of crops, but rarely more than three or four. At this stage the tongue is usually thickly coated. The pyrexia usually persists for a few days after the appearance of the rash; sometimes it is septic in type; more often it does not rise above 101° or 102° F., and drops within a week to normal, as a rule. Until this stage there is very frequently myocarditis, or rather parenchymatous degeneration of heart muscle, the heart dullness is increased, and there is a soft systolic murmur at the apex, but this usually disappears in two or three weeks. There is occasionally albuminuria. The convalescence is often prolonged on account of the severe anemia which frequently results from the infection.

Chronic Streptococcus Arthritis, by D. J. Davis.—See this Journal for June 28th, p. 1370.

The Essentials of Sanatorium Treatment of Tuberculous Gravidæ and Puerperæ and Their Children, by L. S. Bacon.—See this Journal for June 28th, p. 1369.

Physiology of the Pylorus, Pileus Ventriculi, and Duodenum as Observed Röntgenographically, by L. G. Cole.—See this Journal for June 28th, p. 1370.

A Study of the Spinal Fluid in One Hundred Cases of Syphilis: Including Investigations for Arsenic after Intravenous Administration of Neosalvarsan.—M. F. Engman, R. Buhman, F. D. Gorham, and R. H. Davis state that as the result of their studies in these cases, thirty-six of which were of early syphilis and sixty-four of late syphilis, it would seem to be shown that, 1, only comparatively small proportion of those infected by the Spirocheta pallida give serological and cytological evidence of cerebrospinal invasions; and 2, when such an invasion does occur there are usually early clinical manifestations of it, which substantiate clinical observation. In the endeavor to determine whether, if some of the spinal fluid were removed and an intravenous injection of neosalvarsan followed immediately, the fluid removed would not be replaced with a fluid surcharged with arsenic, four cases of paresis were selected; and the results were negative in all four instances.

Chronic Adherent Pericarditis.—From a study of sixty-two cases W. H. Smith arrives at the following conclusions: 1. It may be said that adherent pericarditis is impossible of diagnosis (which is unimportant under such conditions) in cases unassociated with cardiac symptoms, cardiac enlargement, or murmurs. 2. In a second type, in young adults, adhesive pericarditis, which is of serious import, is apt to be overlooked because the coincident endocarditis appears in the foreground. This affection should always be thought of in a young adult whenever rheumatism followed by endocarditis appears in the history, and especially when the cardiac failure is more marked or the cardiac enlargement more extensive than the endocardial damage seems to warrant. 3. More careful records should be made of the presence or absence of cardiac dilatation in cases of acute rheumatism without endocarditis or pericarditis.

Some Features of Röntgenographic Changes in Pituitary Diseases.—Alfred Luger says that, in general, it may be said that conclusions in regard to disorders of the pituitary can be drawn only from the changes in the bony parts. It is of great importance to note that the order of appearance of the changes in the sella turcica is quite different in the case of a tumor of the pituitary gland itself, on the one hand, and tumor of the hypophyseal stalk, or other pathological condition of the immediate neighborhood of the gland, on the other. Having described the sequence of changes respectively in the two classes of conditions, the author states that in tumors of the brain which have no relation whatever to the pituitary, and in the case of internal hydrocephalus, there are not infrequently found changes due to the increase of intracranial pressure which are very similar to those met with in extrasellar tumors. In large tumors of the sella the so-called sphenoparietal sinus is often enlarged; which can be explained by the pressure of the growth upon the sinus cavernous. In tumors of the acoustic nerve a rather characteristic change in the dorsum sellae has been noted; they sometimes produce not only a thinning of the dorsum, such as is observed in other extrasellar growths, but also a tendency of the dorsum to incline forward. All these examples show that changes of the sella turcica in size and shape occur rather frequently in conditions other than true pituitary tumors; but, on the other hand, the great influence of the other ductless glands on the development of the pituitary, and on the secondary changes of the sella turcica, has been demonstrated.

Unique Wrist Injury: Recurrent Anterior Dislocation of the Ulna.—A. C. Yoder reports this case, which makes the eleventh of the kind recorded. In summing up the diagnosis of the case he enumerates the following points: 1. Fracture and disappearance of the ulnar styloid; 2. recurrent forward dislocation of ulna, with probable rupture of triangular fibrocartilage; 3. subluxation, dorsally, of the radiocarpal joint; 4. crowding together of many of the carpal bones; 5. possibly a slight subluxation of semilunar and os magnum. The prognosis, he says, is good as to function, but absolutely bad with respect to restoration of parts.

MEDICAL RECORD.

September 6, 1913.

Lead Poisoning in New York City.—J. S. Kenney presents a study of twenty-five cases of lead poisoning, with special reference to industrial hygiene from the dispensary standpoint. These cases were seen at the Cornell dispensary, where about one year ago, at the suggestion of Professor W. G. Thompson, a somewhat systematic study of trade diseases was begun with the view of gaining facts and information as to the extent of these conditions, how they were brought about, and other useful knowledge which might aid in their preven-
tion and control. In order to make hazardous indus-
tries more endurable and safer for wage earners
the author believes that there should be carried on
a nation wide campaign, both legislative and educa-
tional, on the same lines as the fight against tuber-
culosis. The suggestions he makes are: 1. The
education of the worker and the employer; 2. legis-
islative control along certain lines; 3. the enlistment
of hospitals and dispensaries in the work. Included
in the paper is a copy of a circular issued by the
Cornell dispensary containing specific instructions
for persons exposed to industrial diseases, espe-
cially lead.

The Psychoanalytic Delusion. The Sexual In-
fantile.—J. V. Haberman criticizes in a very
cautious manner the theories of Freud and the at-
titude of his followers, asserting that "the psycho-
analyst assumes in the absolute, is ever unerring,
stretches and amplifies in terms elastic, and pities
and commiserates the little oil aglow within one's
uninitiate attic." This, he says, is the ring to be
heard more or less plainly in the expounding of
our Freidists, or a gradually growing group of
such enthusiasts on this side the Atlantic. After
a review of the past and current literature, in which
he quotes the opinions of a large number of writers,
he remarks: "These citations, aggregated, amply
confirm, and without further argument, the criti-
cism intimated at the outset of this paper that the
supposition of a sexual infantile or childhood's
trauma as the causation of hysteria is utterly un-
tenable, and that this is the opinion maintained by
the authoritative writers on this and allied subjects
and the neurological world at present."

Is There Value in Electrotherapeutics?—In
some communities and in some medical circles, Wil-
liam Martin says, this would be answered in the
negative. It is to be regretted, however, that there
should be any question at all, since the value of
properly applied electrotherapeutics has been am-
ply proved. The fact that so many of the profes-
sion know so little of these modern therapeutic
methods is traceable to two causes. First, the fault
lies with the medical colleges; and the second rea-
sion is the direct result of the first. Because the
regular profession has not been educated up to a
working knowledge of electrotherapeutics, it has
been taken up by charlatans and quacks, who have
exploited it to their financial advantage. What ap-
lies to electrotherapy applies to all the other phys-
ical measures; there must be some good in each,
or there would be no results of a satisfactory na-
ture. The author takes up in succession some of
the more important conditions which best respond
to the application of electric modalities. Cardio-
vascular supertension, so frequently seen as the re-

tult of toxemias, can be readily relieved, particular-
ly when recognized prior to organic changes; and
in all cases of supertension, whether early or late,
at least something can be done for relief of the ur-
gent symptoms. Hardening of the arteries, which
seems to be an accompaniment of the modern meth-
ods of living, and due frequently to toxemias, can
be prevented from advancing by the use of the high
frequency current given by the autocondensation
method, and some physicians feel warranted in stat-
ing that this condition can even be measurably re-
moved. Under this method of treatment it is sur-
prising to note the remarkable improvement, both
mentally and physically, which takes place, due to
the removal of the great strain from the cardiovas-
cular system. In neuritis not only is the inflamma-
tion relieved, but the plastic exudate is broken up
and absorption promoted. Even when more or less
nervous cell degeneration has resulted, with or with-
out muscular atrophy, a cure may be hoped for. In
the treatment of rheumatism, osteoarthritis, gout,
and allied ailments electricity is a valuable adjunct.
Prostatic hypertrophy has recently been success-
fully treated by electrical methods, and this natural-
ly has opened a wide field of usefulness, owing to
the great mortality following prostatectomy. Other
classes of afflictions in which the value of electricity
is spoken of in the paper are diseases of the ner-
vous system, chronic skin diseases, and conditions
of lowered vitality and altered metabolism such as
are met with in chronic digestive faults involving
the liver and other organs.

AMERICAN JOURNAL OF THE MEDICAL SCIENCES.

Experiences with Steinmann's Nail Extension
Method in Fractures of the Femur.—The essen-
tial part of this method, as explained by John C. A.
Gerster, consists of a nail which transfixes the soft
parts and bone, and which is the sole point of at-
tachment for suitable traction upon the lower frag-
ment. In other words, the bone and soft parts are
transfixed by a drill, which is left in place with
both its ends projecting. In certain cases nail ex-
tension is the only method to be used; in others it
is an aid to previously existing methods. In recent
fractures it is indicated wherever the usual traction
methods fail. In old fractures, the fact that nail ex-
tension can be employed with success, at a consid-
erable time after the fracture has occurred, makes
it of value when a fracture is complicated by ex-
tensive abrasions of the skin or by acute disease.
In malunion with much overriding, operation fol-
lowed by the Steinmann method is the only way in
which an ideal result can be safely obtained. As
a preliminary to Lane plating, in cases where that
method is indicated, nail extension is excellent.
Synopses of twelve cases in which the method was
employed are appended to the paper.

The Relations of Internal Secretion to Mental
Conditions.—L. V. F. Hochwart takes up in
succession, in this connection, the genital glands,
the thyroid, the thymus, the pituitary, the pineal
gland, the pancreas, and the suprarenals. From this
review he says it will be seen that we know a num-
ber of the effects of internal secretions on men-
tal conditions, and how the development of the mind
depends on these secretions. Brain anatomy
helps but slightly in showing how higher mental
development is to be explained. Perhaps the time
will come when we shall learn to perceive how much
depends on the individual structure of certain
glands and on their individual internal secretion.

An Experimental Study of Sodium Bicar-
bonate and Other Allied Salts in Shock.—As a
result of this experimental study, M. G. Seelig, J.
Tierney, and F. Rodenbaugh state that since none
of the factors of bulk, hypertonicity, alkalinity, or
free carbon dioxide gas showed itself the sole cause of the pressor effect of sodium bicarbonate, they were forced by exclusion to assume that this salt acts specifically upon the heart muscle. This assumption receives corroboration from the fact that, with both vagi cut, and even with all the higher cerebral centres destroyed by Jackson's method, an injection of sodium bicarbonate is followed by a rise of blood pressure.

An Intensive Study of the Epidemiology of Pellagra; Report of Progress.—Joseph F. Siler and Phillip E. Garrison, of the Thompson-McFadden Pellagra Commission, conclude an elaborate report on this subject, which was begun in the July issue. Among the epidemiological data which are summarized at the end of the report are the following: Density of population, while showing a tendency to conform to the relative prevalence of the disease, does not alone offer an explanation of the geographical inequalities of its distribution within the county (Spartanburgh, South Carolina). The cotton mill village population gives a rate of prevalence of 104 per 10,000, against 19 per 10,000 for the remainder of the county, and against 16 per 10,000 for the rural sections alone. Excluding the mill village population (which is practically all white), the remaining white population still gives a rate of prevalence over two and a half times that among the negroes. The rate per 10,000 for males in the county is seventeen; for females, 50.5. The rate among children under ten years and adults of forty-five and older is practically equal in the two sexes. In both males and females there is a striking fall in prevalence between the ages of ten and twenty. The most significant fact with regard to occupation is the excessive prevalence of pellagra among women employed in housework. The excessive prevalence of pellagra in the mill village population is found largely among women and children at home during the day. Among actual mill workers the rate of prevalence between the two sexes appears to be about equal. Climatic conditions appear to influence the development of symptoms of the disease. The absence of properly constructed privies and the almost complete absence of effective screening of dwellings present a situation highly favorable to the transmission of disease organisms eliminated in the excreta, both by direct contamination of food and person, and by insects. The most striking defect in the general dietary of the working classes appears to be the limited use of fresh meats, but investigation of the kind, quantity, and quality of corn and corn products used, failed to bring to light any epidemiological evidence pointing to the agency of corn as an etiological factor in the disease.

Pinching the Appendix in the Diagnosis of Chronic Appendicitis.—A. Bassler says that while McBurney's point is undoubtedly of much value in the diagnosis of appendicitis, the sign fails at times. He recommends that, if the patient is not too stout, the lower border of the cecum should be percussed for. With an estimation of about where the appendix would be, as judged from the location of the lower end and sides of the cecum, pressure on the abdomen should be made at that point. A second plan (which is applicable whether the cecum can be mapped out or not) is to palpate for the right edge of the rectus muscle—a matter which is facilitated by having the patient rise to a sitting posture. This site is maintained with a finger, and the thumb placed vertically on the abdomen, its tip pointing to the eniform cartilage. It is then slowly pressed backward into the abdomen, and when it has been sunk about halfway down to the back of the abdominal cavity it is swung to the right of the patient, at a right angle to the downward pressure line. This pinches the appendix against the iliacus muscle and the unyielding structures about it, and usually elicits pain or tenderness.

American Journal of Obstetrics and Diseases of Women and Children.

Emptying the Uterus as a Means of Treatment of Puerperal Eclampsia.—Reuben Peterson refers to the difficulty in restraining one's enthusiasm over some special kind of treatment in a few cases of eclampsia, which has reduced the maternal mortality to five or ten per cent. He also calls attention to the fact that we have no means of estimating the severity of the eclampsia in the patients who survived such treatment. The severity or the number of convulsions being no criteria of the degree of intoxication from the eclamptic poison, since patients have lived after many convulsions under all kinds of treatment and have died after one apparently mild convulsion. Inasmuch as the condition is due to pregnancy it would seem that the emptying of the uterus were the rational method of treatment. Through an examination of a large number of cases Peterson found that prompt delivery gave a maternal mortality of 15.0 per cent, as compared with a maternal mortality of 28.0 per cent where the delivery was long delayed. If the uterus is emptied immediately or very soon after the onset of the first convolution, the maternal mortality is still lower. Peterson therefore concludes that the treatment of antepartum eclampsia should consist of emptying the uterus as quickly as possible after the onset of the first convolution.

Ovarian Teratoma.—White briefly reviews the types of teratomata and the theories concerning their formation and then reports in some detail two instances. The first case being in a girl of four years, the second in a woman of thirty-two.

Leucoplakia Uteri.—Sweeney reports a case of this unusual condition and believes that it is the result of a metaplasia of epithelium, the columnar type being replaced by the squamous variety.

Archives of Internal Medicine.

Hydrogen Ion Concentration of the Urine in Heart Disease.—H. H. Newburgh, W. W. Palmer, and L. J. Henderson found that the hydrogen in concentration of the urine from individuals with severe cardiac decompensation is higher than normal. It follows the general clinical course, becoming normal when compensation is restored.

Acid Base Equilibrium and the Nature of Acidosis.—W. W. Palmer and L. J. Henderson present evidence favoring the view that varying grades of acidosis may exist, apart from diabetes.
and cases in which beta oxybutyric acid is produced in many pathological conditions not previously suspected. In many pathological conditions the administration of an alkali makes the patients feel better. It should be given in large amounts (if sodium bicarbonate, four grammes three or four times a day) until an effect on the urinary acidity is noted, and thereafter only in sufficient quantity to keep the reaction of the urine slightly more acid than the blood. If a marked reduction in urinary acidity occurs, alkali is not indicated. The authors describe a relatively simple method of determining the urinary acidity.

Effect of Diuretic Drugs in Severe Acute Nephritis.—Chandler Walker and R. P. Dawson found that diuretic drugs such as thecin, caffeine, and potassium acetate, definitely shorten the life of a rabbit having a severe acute experimental nephritis produced by uranium nitrate. Thecin and potassium acetate gave quite parallel results and were slightly more harmful than caffeine. Sarpentine sulphate, although not nearly so detrimental as the other drugs, did in some cases shorten the animal’s life. Water in large amounts is detrimental in some cases, possibly depending on the severity of the nephritis. The diuretics alone in large doses, and water alone in large doses, when given intravenously to normal animals for a reasonable length of time do not shorten their life, and probably are not toxic in themselves. Diuretics are probably contraindicated in severe acute nephritis in man, since in animals in such cases they shorten life.

Bacteriology of the Duodenum.—W. J. MacNeal and A. P. Chace found it possible, with care, to obtain a sample of the intestinal juice through the Einhorn duodenal tube sufficiently free from contamination for bacteriological study. They conclude that normal duodenal fluid during a fast is almost free from living microorganisms, although numerous dead bacterial cells are always visible on microscopical examination. In various gastric and intestinal disturbances, the number of cultivatable microbes is markedly increased, these including bacilli, cocci, yeasts, and branching thread forms. In the one case of typhoid examined, Bacillus typhosus was isolated. Such a study of the intestinal juice would seem worth while in achylia gastrica with diarrhea, in cholecystitis, probably in the obscure diseases sometimes ascribed to abnormal intestinal digestion, and perhaps, for purposes of early diagnosis in typhoid fever and for the detection of typhoid carriers.

Case of Acromegaly and Polyglandular Syndrome.—F. K. Bartlett reports a case presenting the following pathological conditions: (1) Chromophil cell adenoma of the anterior lobe of the hypophysis; (2) persistent and noninvolved thymus; (3) colloid goitre with marked desquamation of the parenchymatous cells; (4) hypertrophy of the chromaffine cells of the adrenal medulla; (5) hyperplasia of the endothelial elements of the lymph nodes and of the spleen; (6) enlargement of the pineal body; and (7) atrophy of the cells of Sertoli and of Leydig. In this case the hypophysial disorder probably underlay the disturbances of the other internally secreting glands, while the lymphoid hyperplasia was indicative of Pauloff’s status thymolymphatics. The condition of the pineal gland, which was over twice as large as normal, was of special interest, though it cannot be determined whether its enlargement was primary, or secondary to the hypophysial disturbance.

Variations in Thyroid Colloid in Conditions of Hyperthyroidism and Hypothyroidism.—A. P. Jones and A. L. Tatum found the iodine content of the thyroid of rabbits increased directly by the feeding of commercial desiccated thyroids, and indirectly, by intravenous injections of serum from hyperthyroid of rabbits. It was decreased, on the other hand, by intravenous injections of serum of thyroidectomized rabbits. After injections of normal serum, the iodine content was sometimes increased, sometimes decreased, or remained constant, indicating individual variations in thyroid activity.

MONTHLY Cyclopedia AND MEDICAL BULLETIN.

July, 1913.

Treatment of Chronic Antral Suppression.—E. B. Gleason describes a new trocar, one end of which is probepointed and the other a triangular sharp point, for the production and maintenance of a comparatively large opening from the maxillary antrum into the nose beneath the inferior turbinate body. On the concave surface of each of the slightly curved tips, for a distance of 1 3/4 inches, is a coarse file or rasp so disposed as to cut only on the pull. Where, upon thrusting a hollow needle through the “soft spot” beneath the inferior turbinate, the irrigation fluid returning is observed to contain pus, the triangular point of the trocar is placed in the needle puncture, rotated until it penetrates to the lateral wall of the antrum, and the anterior edge of the opening cut away with the rasp until an orifice larger than a ten cent piece is obtained. The antrum is irrigated daily by the surgeon through a Eustachian catheter, until the patients learn to insert the catheter into the antrum and irrigate himself. One or two pints of normal saline solution are used each time. Cure is greatly hastened by the constant drainage of the antrum into the nose through the large opening made.

Spondylolthesis.—Albert Abrams cautions against exhausting the aortic reflex of contraction—elicited by percussion of the seventh cervical spine—by too frequent treatments in aortic aneurysm. One should not expect results in a less period than one month. By means of the pyloric reflex of dilatation, produced by pressure or concussion of the fifth dorsal spine, introduction of the stomach tube into the duodenum can be rendered easy, immediate passage of drugs from the stomach into the intestine caused, the nausea incident to ingestion of drugs avoided, indigestion of starchy foods prevented, vomiting often at once arrested, and symptoms due to gastric indigestion often relieved by causing the stomach contents to pass into the duodenum. Pressure at the eleventh dorsal spine straightens the sigmoid flexure and allows passage of a colonic tube beyond this portion of the gut. The author has seen three patients with chronic endocarditis “cured” by injections of fibrinolysin coupled with concussion of the seventh cervical spine to elicit the cardiac reflex of contraction—this being practically a method of heart gymnastics.
Surgical Aspects of Furuncles and Carbuncles.
—P. G. Skillern, Jr., says that to incise a boil in its hard stage is merely to carry the virulent, infecting bacteria through the barrier of leucocytes into healthy tissues and is wholly illogical. A most successful treatment in the hard stage is to shave the skin wide of the boil and without abrading it. Then bathe the area thoroughly first with benzoin and then with alcohol. Paint with strong tincture of iodine, or three per cent. alcoholic solution of picric acid. Now scratch the cap off the vesicle with the point of a knife, boring a little into the centre of the boil if the exposed orifice is not larger than the shaft of an ordinary pin. Next secure gentle suction with a Bier cup for three minutes. Repeat in four hours. This withdraws some of the infected fluids and bathes the boil with fresh blood. Dress with a drain poultice made of gauze saturated with an isotonic solution, which prevents the clotting of blood or serum in the pit at the centre. Wright's solution is suitable, and consists of sodium citrate, one per cent., and sodium chloride, two per cent. Cover with waxed paper to retain the moisture; apply a cotton compress over this to make the pressure uniform, and secure with a muslin bandage. Have the patient keep the gauze wet with the solution. The boil will expel its core under this treatment in from one to four days, and, thereafter, heals rapidly, leaving a minute scar which is scarcely visible. If the boil has been squeezed, or if there is fluctuation due to free pus, it should be incised. In every case treat with an autogenous vaccine to prevent furuncular recurrence.

Proceedings of Societies.

THE THIRTIETH ANNUAL MEETING OF THE AMERICAN CLIMATOLOGICAL ASSOCIATION.

Held in Washington, D. C., May 6, 7, and 8, 1913.
The President, Dr. Charles L. Minor, of Asheville, in the Chair.

The Address of the President: A Retrospect and a Prospect.—Dr. Charles L. Minor, of Asheville, spoke in part, as follows: "A whole generation has elapsed since the founding of this society and in so progressive a profession as ours twenty-nine years bring changes so great as to almost revolutionize it, through the opening up of new territories and the development of new ideas. Bacteriology, asepsis, antisepsis, the whole brilliant hypothesis of immunity and its evolution of serum and vaccine therapy, laboratory diagnosis, and the knowledge of tuberculosis marks the steps in our progress. When such changes occur in so short a time it is evident that only by constant growth, and by adaptation to new conditions, can medical men and medical societies hope to keep abreast of the times. It seems to me that I might well devote the time of the presidential address, not to the consideration of medical topics, but rather to a review of our past, that from it we may draw inspiration and suggestions for our future. Few of us have had time to inform ourselves of the work that our predecessors have done in this society; if we did, we would be surprised at the amount of valuable material that has first seen the light here. The study of tuberculosis has taken a large place in our work, and the future historian of the tuberculosis campaign in the United States cannot afford to ignore what has been done by the members of this society. But we should not be chiefly a society for the study of tuberculosis, but we should take pride in the fact that we have been active and prominent in founding the National Association for the Study and Prevention of Tuberculosis. Again we have a right to feel proud of the admirable work on diseases of the lungs and heart which has been done here, and especially on the physical diagnosis of those diseases. Again, our various mineral springs have been carefully studied and much information as to their qualities has been collected, though we are far from having the full information obtainable about the various European hydrotherapeutic resorts, and there is a movement in Congress now, for which our support is requested, to have the springs of the United States carefully analyzed. If we desire in the future, as in the past, to hold an honorable place among American medical societies we should critically study present conditions in order to see what we can do to advance our association. We should admit only men whose positions are established and who have a right to apply. We have reached a critical period in the history of this society, and climatology, even with the powerful addition of diseases of the lungs and heart, no longer offers a sufficient field for the activities of the society. We must widen our borders and let it be known that climatology is not the chief centre of our interests. We must feel ourselves free to study all subjects within the realms of clinical medicine; only so can we hope to keep up with the march of modern medical progress. There is, therefore, a very real demand for a society strictly clinical in its aims and scope, and where all men interested in general clinical medicine, of which climatology is only a small part, can bring their problems for discussion. The members of the society must realize that not good fellowship alone, but the ability and willingness to do first class clinical work and to read strong papers will be necessary for entrance into our ranks. Let us call our Association the American Climatological and Clinical Association, or possibly better, the American Clinical and Climatological Association. Let us amend our constitution so as to open our meetings to the discussion of all topics of general clinical medicine."

On the Auscultatory Determination of Early Pathological Changes in the Lungs.—Dr. Henry Sewell, of Denver, briefly summed up the evidences that had been presented as follows: 1. Auscultation was capable of giving the earliest subjective information of physical changes in the lungs. Such a study demanded analysis of the sound into those vibrations due to resonance of the viscera and those of the chest wall, and that the latter vibrations could be damped by pressure of an appropriate form of stethoscope. 3. Vibrations transmitting the whisper were confirmed almost wholly to the viscera. 4. The modification of the voice sounds...
by which their quality became more amphoric and their duration prolonged into an echo were the striking characters which, when accentuated by stethoscopic pressure, indicated pathological changes in the visera. 5. The character and distribution of vocal signs over the normal chest were sufficiently constant, so that a topographical study of the chest by auscultation may definitely suggest, through recognition of departure from the normal, the intensity and distribution of morbid changes within the lungs, even when these changes were too slight to appeal to the senses through any other methods.

 Auricular Flutter, with a Report of Three Cases.—Dr. FRANK TAYLOR FULTON, of Providence, explained that this was a term which was applied to a condition characterized by an extremely rapid action of the auricle, the rate being usually somewhere between 200 and 330 to the minute. It was the result of some pathological impulse formation. The ventricular action might be varied. There was always some grade of heart block. The ventricular rate commonly was one half that of the auricle. Flutter was closely related to fibrillation, as well as to regular tachycardias of less rapid rate than itself. The condition had been considered as rare, but the electrocardiograph had demonstrated that it was probably not very uncommon. It might be detected by the use of the polygraph. It was not necessarily a permanent condition; the heart action might return to normal and remain so for a long time. Richie divided the cases of flutter into four groups. (1) Those in whom there might be or might not be other signs of cardiac disorder but in whom the symptoms could be ascribed to the increased auricular rate and the consequent rapid ventricular action. (2) Cases with a history of old standing cardiac disease with general edema and in whom flutter developed. (3) Cases in which there was a fairly marked degree of heart block, as in the case of Hertz and Goodhart, so that the ventricular rate from the onset was slow. (4) Cases in which flutter might develop where there was complete dissociation of the auricular and ventricular rhythm.

The Effect of Climatic Changes on Rheumatism and Neuritis.—Dr. JAMES DUDLEY MORGAN, of Washington, stated that there was much confusion as to what effect meteorological changes had on certain disorders and what would help some of the more common diseases. The effects of winds, seasons, climates, and localities as an influence on disease was recognized in the time of Hippocrates. Hipparchus had also written of climates and divided them, so far as they were known, into eight, extending from Merceq to the Nile, and to including the British Isles. However, the literature in reference to the effects of climate on rheumatism, gout, and neuritis was astonishingly meagre. This paper did not presume or attempt to show that rheumatism was caused by any other factor than infection, but tried to draw a correlation between the primary attack and the weather, and the tendency of recurring attacks to be associated with changed conditions of the atmosphere. Some writers had seemed to see a relation between humidity and rheumatism, while others believed that there was no marked coincidence between the cause of rheumatism and the rainfall. Neither was it more common at the two extremes of life. Rheumatism had been found to be more prevalent in a moderately low temperature accompanied by moisture. Beside moisture and temperature, ventilation seemed to have much to do with the prevention of rheumatism. One could not say too much of the advantage of ventilation and a locality that was open and airy. There was a popular idea that rheumatism, neuralgia, and gout were made worse by an approaching storm, and there seemed to be some foundation for this belief in certain cases that were on record.

Climate of the San Diego, California, Region with Relation to Renal Disease, by Dr. P. M. CARRINGTON. This paper appears in this issue, pp. 559 et seq.

Clinical Observations on Blood Pressure.—Dr. JUDSON DALAND, of Philadelphia, remarked the frequency of errors in the making out and interpretation of blood pressure records suggested the desirability of bringing up this subject for discussion. The mercurial sphygmomanometer should be preferred to the small spring sphygmmomanometer because of its accuracy. Diastolic pressure observations were often omitted, whereby valuable information obtained from a study of the low and mean pressure was lost. Too often but a single blood pressure record was made, although it was often necessary to observe the effects of work, rest, sleep, and emotional excitement. The most important factor, clinically, was the state of the vasomotor system. Physiologically, blood pressure varied at different times of the day and was influenced by rest, cerebral, or muscular work, and emotional or psychical excitement. Variations thus induced were modified by disease. A sudden unexpected noise had produced a sudden temporary increase in blood pressure of from 20 to 30 mm. A correct interpretation of blood pressure records, especially in those of nervous temperament, required not only the selection of a proper instrument and proper technic, but also that the patient be under average physiological conditions. Multiple blood pressure examinations were often necessary before sufficient data were secured upon which to base a proper interpretation. Idiosyncrasies regarding blood pressure might be expected analogous to those observed in the pulse rate, the respirations, and the temperature. Temperament played an important role in the production of variable and high blood pressure. No patient of nervous temperament should be examined immediately after arriving at the physician's office, unless a control observation was made later, and any evidence of haste or excitement should be avoided. The first observation was made in the sitting posture, the second after reclining for a few minutes, and the third immediately after making ten vigorous bending movements, touching the floor with each movement.

An Inquiry into the Cause of Bronchial Asthma.—Dr. ROBERT H. BARCOCK, of Chicago, suggested that, in order to facilitate discussion, the etiology of bronchial asthma be divided into two clinical forms. In one the paroxysms of dyspnea first made their appearance in early childhood and henceforth occurred with varying degrees of periodicity. The paroxysms usually lasted a variable length of time and were in most instances arrested by some particular remedy. During the interval the patient was usually free from dyspnea and felt entirely well. The individual might be permanently
relieved by a change of climate, especially when the exciting agent was found in some particular plant, though in some cases change of climate proved remedial, even when no special irritant could be identified. In every case of asthma one should search for some form of chronic infection of the nasal accessory sinuses, in a chronic hyperplastic ethmoiditis, or in some closed cavity in any other part of the body, and, finding it, advise its removal by surgical interference. If the asthma was traceable to some form of animal or vegetable emanation, or to some article of food to which the individual had become sensitized, one could only advise the avoidance of exposure to the exciting cause.

What Relation, If Any, Have the Tonsils to Pulmonary Tuberculosis.—Dr. E. Fletcher Ingals, of Chicago, said that it was formerly stated that the tonsils were a common portal of infection for pulmonary disease, but subsequent research had demonstrated that the tubercle bacilli might penetrate the tonsils and pass through them to the lymphatic cervical glands, causing tuberculosis of the latter, without any involvement of the faucial tonsils. It had been shown that there was no connection between the cervical glands and the pulmonary lymphatics. In a small proportion of cases the tonsils seemed to be primarily involved in the process of pulmonary tuberculosis, but usually tuberculous changes in these glands were secondary, and the bacilli seem to have been absorbed from the sputum. It had been shown that the tonsils were the port of entry for the tubercle bacilli in many cases of tuberculous cervical adenitis. The consensus now was that pulmonary tuberculosis was generally a systemic infection of aerogenous origin, and that when the tubercle bacilli were taken up by the lymphatics they were poured into the general circulation. In pulmonary tuberculosis the bronchial glands might be primarily involved, but this did not seem to be the usual course of the disease.

The Nutritional Effect of Intermittent Albuminuria of Adolescence.—Dr. Fremont Smith, of Washington, reported two cases of transitory albuminuria occurring in lads, one seventeen years of age, and one twenty-one. Both had been under observation for ten years. The elder had entirely recovered. From the opinions of certain authors as well as from his own experience, not only with these two cases, but with others which he had been able to follow for a less period of time, the evidence seemed to be conclusive that transitory albuminuria, intermittent or remittent in character, had little or no effect upon the nutrition of the child.

The Fruits of Laboratory Work in Relation to Clinical Tuberculosis.—Dr. Edward R. Baldwin, of Saranac Lake, remarked that the habit of making distinctions between clinicians and laboratory workers had grown up of late, and the result had been unfortunate in some respects. On the one hand there was the inability of the pure clinician to appreciate the laboratory specialist; and, on the other hand, a contempt for the art of medicine, at least the empirical side of it, had ensued on the part of the laboratory man. The fruits of laboratory work in relation to tuberculosis went back to Villemin in 1865 and to Koch. It was true that much time had been given to laboratory work, but so was it with the physician at the bedside. False deductions in the laboratory, as well as at the bedside, had cost men their lives. That was why medicine had blundered along toward an exact science but had never reached it. Probably no single fruit ever equaled the discovery of the tubercle bacillus in importance, and a close second was tuberculin, the value of which was now being appreciated. As an addition to treatment tuberculin had not been such a boon, but in revealing the enormous number of infected individuals, both human and bovine, the whole programme of tuberculosis prevention had been influenced. The idea of inheritance was so dominant in the past, that it was painful to think of what would have happened but for Koch's work. The laboratory had aided both directly and indirectly in the diagnosis of tuberculosis in addition to the discovery of the bacillus.

A Year's Observations on Symptoms in Cases of Advanced Tuberculosis in the Los Angeles County Hospital, in Connection with Weather Conditions.—Dr. Charles C. Browning, of Los Angeles, said that in 1908 he reported some observations to this society regarding the apparent influence on temperature and hemorrhage in tuberculous patients with reference to certain meteorological phenomena. It appeared from that report that unseasonable, or very sudden changes in temperature appeared to influence the temperature of the patients, while equal or greater changes occurring slowly did not. Of the cases of hemorrhages reported it appeared that these tended to occur in groups, about four times the number occurring when there was a barometric pressure change exceeding three tenths of an inch within twenty-four hours than when the barometric change was less. The hemorrhages seemed to be more frequent if there had been a decided change in one direction, a sudden fall. On this occasion he wished to call attention to some observations extending over a year on tuberculous patients, and to present charts showing the scope of the work. During the year there were recorded 21,968 patient day observations, with an average of sixty-one patients charted daily. There was an average of about seventy patients in the wards, but there were a number who were not noted. Hemorrhage and death groups were quite noticeable during some months, but not during others. There were recorded 217 hemorrhages, six of which were fatal, and 227 deaths. Climatic conditions could only act to a certain extent as determining factors in producing the symptoms recorded. The conditions which appeared to influence groups of hemorrhages and deaths appeared to be barometric pressure, humidity, and cloudiness, each in its turn appearing to be the most prominent index to weather conditions, which seemed to exercise a limited determining influence as the charts demonstrated.

The Influence of Smoke on Acute and Chronic Lung Affections.—Dr. William Charles White and Dr. Paul Shuey, of Pittsburgh, observed that their mortality statistics were based on the mortality statistics received through the courtesy of Dr. C. L. Wilbur, chief of the Division of Vital Statistics of the United States Census Bureau, and also through the courtesy of the boards of health of various cities. Smoke as a problem of health had its main influence upon the respiratory pas-
sages. Pneumonia and tuberculosis had been studied from a statistical standpoint for various cities scattered throughout the United States, and comparisons made with the city of Pittsburgh, which probably had the greatest number of smoky days in the year. In considering the influence of smoke on acute and chronic fatal lung infections, the question of age distribution; age of city; poverty on a basis of congestion; and topography of the city had been taken into account. The latter feature in such a city as Pittsburgh, with high walls and river valleys, allowed a partial segregation of the city into areas of varying smoke density. In other cities the contour did not allow such divisions. The chief tendency of the study seemed to indicate that smoke had a rather severe influence on pneumonia, with a much less influence on tuberculosis.

The Role of Physical Exercise in the Open Air in the Prophylaxis of Tuberculosis.—Dr. James M. Anders, of Philadelphia, showed that there was a disposition on the part of the physician to overlook the importance of muscular exercise in the prophylactic treatment of pulmonary tuberculosis, since the general acceptance of the principle of rest in all cases of this disease in which fever was present. He did not attempt to underrate the great value of rest in the active stages of this disease, but rather to emphasize the importance of systematic muscular exercise as a means of minimizing the number of susceptible persons.

The Two Most Important Factors in the Treatment of Tuberculosis.—Dr. Delancey Rochester, of Buffalo, stated that the mortality from tuberculosis had diminished to a considerable degree in those localities where a vigorous antituberculosis campaign had been waged and this showed that more cases had been recognized in a curable stage and, by proper methods of treatment, had been cured. There were, so far as could be learned, no reliable statistics as to the incidence of the disease, so that we did not know whether there had been a lessening in the morbidity of the disease or not. Personally he believed there had been no such lessening. Instruction in regard to the destruction of sputum and feces, in regard to precaution as to personal contact with others, and in regard to apartments recently occupied by the tuberculous, were all of value in checking the spread of the disease, but there should be some plan of compulsory reporting of cases, and compulsory removal of suitable patients into proper sanatoria; this would be much more efficacious than all the other procedures in wiping out the white plague.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Meeting held April 2, 1913.

The President, Dr. James C. Wilson, in the Chair.

The Development of the Nasal Accessory Sinuses in Man.—Dr. Warren B. Davis gave a synopsis of a year’s research work done in the laboratories of Friedrickshain Krankenhaus, Berlin, and in the Daniel Baugh Institute of Anatomy, Philadelphia. The material studied consisted of 145 specimens (290 lateral nasal areas) forming a series covering all stages of development from the sixtieth day of embryonal life to maturity. Numerous lantern slide illustrations made from drawings of selected specimens had been used. Sixty day embryos showed presence of concha inferior, two ethmoidal conchae, and beginning development of the processus uncinitus. The superior concha and processus uncinatus contained at this time no cartilaginous structure. Eighty-five day embryos showed the early development of the bulla ethmoidalis and beginning lateral pouching from the infundibulum ethmoidale which represented the primitive ostium maxillare. There was also in the sphenethmoidal recess an evagination of the mucosa in a posterosuperior and slightly lateral direction, representing the primitive sinus sphenoidalis. In a 137 day fetus this development had distinctly extended into the posterior portion of the cartilaginous nasal capsule. The portion of the capsule forming the anterosuperior wall of the primitive sinus became the concha sphenoidalis or ossiculum. Between the ethmoidal cells developed from the preformed ethmoidal furrows. During the fourth fetal month there appeared cylindrical extensions of epithelium into the lateral ethmoid masses which by the seventh or eighth fetal month became hollowed out and formed primitive ethmoidal cells. The usual number of ethmoidal conchae in fetal and also in postnatal specimens was three; four were not uncommonly present, and in one fetus five were clearly demonstrable. The expansion of frontal cells, of the infundibulum or of the infundibular cells was distinctly seen in late fetal and term specimens, yet in the average case one could not say definitely which expansion represented the primitive frontal sinus until after the sixth month of postnatal life. In the second year the frontal sinus usually began its ascent into the vertical portion of the frontal bone, and in the third year its highest point averaged 3.8 mm. The diameters showed a gradual increase which by the sixteenth year usually reached the average adult size. The sinus maxillaris showed an increase in size which averaged approximately two mm. in both the vertical and lateral diameters and three mm. anteroposteriorly for each year up to the eighth year, after which the increase was less rapid. The floor of the average maxillary sinus after the eighth year was below the level of the nasal floor. The ostium maxillare had no embryological significance. The youngest specimen showing such an opening was four years and three months old. Accessory ostia were present in fifteen per cent. of all cases between four and twenty-five years of age. Accessory ostia were present in 37.5 per cent. of all cases in which tuberculosis was the cause of death, and in only 7.7 per cent. of cases in which death was from other causes. This suggested that the lowered vitality due to tuberculosis might be a predisposing factor in the development of the accessory ostia. In seventy-six per cent. of cases having accessory ostia there were mucous cysts varying from 0.5 mm. to ten mm. in diameter arising in the mucosa lining the medial wall of the sinus maxillaris. The development of the sinus sphenoidalis was found to be more rapid than was described in textbook. It developed in a posterosuperior and slightly lateral direction at first occupying a position anterolateral to the body of the sphenoid and
bounded anteriorly by the concha sphenoidal or ossiculum Bertini. During the second year there was beginning extension into the body of the sphenoid and also a rapid increase in an inferolateral direction, thus bringing the wall of sinus early into close relation with the cranial nerves passing lateral to the body of the sphenoid. The resorption of bone extended medially and posteriorly, and by the sixth to the eighth year had extended beneath the anterior portion of the hypophysis, and the sphenoidal septum had been decreased to about one mm. thickness. Later recesses might extend in any direction, but were most frequently found in the pterygoid processes.

**Principles of Social Service and Their Application in Practice at the State-Tuberculosis Dispensary, Philadelphia.**—Dr. Albert P. Francine observed that the social service work was day-to-day an essential supplement to the medical service of hospitals which bid fair to become a factor quite as important as the hospital work itself. The Department of Health of Pennsylvania had set a standard of efficient and far reaching social service work in the operation of the State Dispensary for Tuberculosis. The system enabled them to follow for years the patients discharged from sanatoria and to carry the principles of prevention into the homes. The cooperation between the dispensary physician and the dispensary nurse could hardly be overemphasized in importance. The nurses were directed to consult personally with the district superintendents of the Society for Organizing Charity or other agencies about the needs of a patient. The cooperation of these charitable organizations was worthy of all praise, yet it was only just and right, since the medical care was given by the State. That a social worker should be also a trained nurse was advisable only in so far as all education and training tended to develop character and ability. The very first thing to do was to impress upon all social service workers, who were all trained nurses, was to adopt the point of view of the social worker and submerge that of the trained nurse. What the physician wanted was an intelligent account of the home conditions. Social service should be made a part of the training of nurses. The theory of social service was to help the patients to help themselves. It was a well recognized principle in their work to induce members of the patients' families to come to the dispensaries for examination, and the work of the nurse was never considered complete until this was accomplished. The fundamental principle of tuberculous dispensary work among the poor was first and foremost to get the patient away to a sanatorium.

**Letters to the Editor.**

**Carbon Oxygen Hydrogen Group Plus Nitrogen, Etc.**

"708 Waldeheim Building, Kansas City, Mo., September 1, 1913.

To the Editor:

In the issue of the **New York Medical Journal** of August 23, 1913, there is an article by J. C. Densten, Ph. D., M. D., under the heading of "Carbon, Oxygen, Hydrogen Group, Plus Nitrogen or Nonmitrogenized and Nitrogenized Food," which contains certain statements that are at variance and in conflict with the teachings of modern physiology and pharmacology.

He says, among other things, that strychnine, morphine, atropine, hyoscyamine, and cocaine, when introduced into the body, become food, furnishing Liebig's "nitrogenized elements of nutrition." A food is a substance which, when introduced into the organism, supplies material that renews some structure or maintains some vital process. It is distinguished from a drug in this respect, that the latter modifies some vital action, but does not supply the material which sustains such action. It is essential, therefore, to the idea of food that it support or increase vital action; while medicines usually increase, lessen, or otherwise modify some vital process. Strychnine, morphine, atropine, hyoscyamine, and cocaine are drugs and not food products; they are not only poisonous and not foodstuffs. These alkaloids do not at all fulfill the requirements of foodstuffs qualitatively, nor quantitatively. Besides, they are not, like the nutritious proloid substances, on the principle of exchange of material, of income and expenditure, converted into the end-products of metabolism, such as, urea, uric acid, etc. When taken internally these alkaloids are again partly eliminated from the body as such, or are partly oxidized and destroyed in the process of tissue metabolism. From these corollaries it is apparent, that is, if things were different from what they are, it would be impossible for the toxicologist to detect these poisons, in cases of poisoning, in the body after death. The average of ten authors gives the following daily quantity of food required for different conditions: Proteids, 121.5 grammes; fats, 82.5 grammes, and carbohydrates, 466.7 grammes. Now, even if it were possible (which, however, is not the case) to utilize these toxic drugs as food the quantity administered would be so infinitesimal as to preclude their use at all and they would for this reason alone be of no value as food whatsoever.

No less an authority than Dr. A. M. Wilson aptly says: "It is a fallacious theory, based on ignorance of physiology, that vegetable medicinal agents are tissue builders, blood makers, or reparative agents. There is not a drug, of vegetable origin, that reconstitutes or vitalizes. All real drugs that act in such a manner are either animal (e. g. pituitrin, adrenalin, thyroidin, etc.) or mineral. The mineral, such as, soda, iron, magnesia, and phosphorus, in an organized state of combination, are normal constituents of the body, and these and other mineral elements, together with a few from the animal kingdom, are the ones to depend upon as recuperatives in all forms of tissue degeneracy.

Theodore W. Schaeffer, M. D.

**Amblyopia Due to Tobacco Smoke.**

216 W. Chestnut Street, Louisville, Ky., September 4, 1913.

To the Editor:

I was interested and rather surprised in the report by Dr. M. L. Foster, and the discussion which followed it, in regard to amblyopia due to tobacco alone. I could certainly relate two, and I think more, cases from my record book of this disease; but instead of giving my own report I glanced at three of the recent textbooks on ophthalmology, taking them without selection just as they came to hand. DeSchweinitz says, in reference to tobacco and alcohol amblyopia: "The disease may be due to either of these substances or to their combined influence," and says: "The disease is more common in tobacco or alcohol users or both combined. The condition results most frequently from overindulgence in tobacco whether in smoking or chewing; occasionally after snuff snuff." Jackson says: Tobacco may cause the disease in whatever way it gains entrance into the system." After giving about a page to tobacco amblyopia alone he considers alcohol amblyopia and goes on to say that in a very large proportion of cases, the disease is due to the joint action of these two poisons. The vital reflexes of the literature on this subject are:

I think, show a case reported by the late Doctor Chisholm, of Baltimore, of a woman who had acquired pure tobacco amblyopia from its use, either as a snuff, or as I recall it, a snuff ball habit of "habit". A word is needed to some extent among the lower classes of the South.

Perhaps these brief references may be of interest to the readers of Doctor Foster's article and of your editorial in regard to it in the Journal of August 30th.

Yours truly,

S. G. Darney, M. D.

The character of this book hardly warrants an extensive review. The author has collected the opinions of numerous authorities in regard to the relative status of the tonsils and the voice, but he has failed to give the references where quotations are made, thereby eliminating the possibility, if in doubt, of substantiating the accuracy of the quotations. The marked scarcity of original material is quite evident, and leads one to believe that the author depended almost entirely upon the opinions of others, as the entire book is practically made up of quotations. The publication of the author's picture in a medical book is quite unusual, and to many has the appearance of quackery. After carefully reading the volume under review, the reviewer cannot help but be impressed with the confusion of ideas, and the absence of any definite or satisfactory classification of conclusions.

In the presentation of the fourth edition of this book, the author has been aided very materially in the preparation of such a work by an unusually large clinical experience. He has sought to make the book, strictly speaking, a clinical guide to the diagnosis and treatment of the diseases of women, by presenting the abnormal conditions as they occur primarily, and in their order of frequency in practice. The work constitutes an extensive, all inclusive, and thoroughly reliable clinical guide for both student and practitioner of medicine. In addition to several hundred illustrations, setting forth, very clearly, the various steps in the surgical technic, the book contains eight full page color plates, also a very general index in the back, rendering almost any information on the subject immediately accessible. Conciseness is a commendable feature of the book. While the most modern methods and technic are fully described and illustrated, not too much nor too little has been written upon any one subject.

Meetings of Local Medical Societies.

Tuesday, September 22d.—New York Dermatological Society; Metropolitan Medical Society of New York City; Buffalo Academy of Medicine (Section in Pathology); Washington Heights Medical Society; Alumni Association of Seney Hospital, Brooklyn; Rome, New York, Medical Society, and Buffalo Medical Society.

Wednesday, September 23d.—Medical Union, Buffalo.

Thursday, September 24th.—New York Celtic Medical Society; Bronx Medical Association.

Friday, September 26th.—New York Society of German Physicians; Manhattan Medical Society; Hospital Graduates’ Club, Brooklyn; Italian Medical Society of New York.

Saturday, September 27th.—West End Medical Society; Lenox Medical and Surgical Society.

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending September 3, 1913:

Anderson, J. F., Surgeon. Detailed to represent the Service at the annual meeting of the American Public Health Association, held in Colorado Springs, September 8 to 13, 1913.

Baughman, D. S., Assistant Surgeon. Granted seven days’ leave of absence from August 24, 1913, under paragraph 195, Service Regulations.

Carrington, F. M., Surgeon. Upon being relieved by Surgeon M. J. White, directed to proceed to San Diego, Cal., and assume charge of the medical care of the same and the medical inspection of arriving aliens at that port.

Clark, T., Surgeon. Granted ten days’ leave of absence from August 28, 1913.

Cofer, L. E., Assistant Surgeon. Granted ten days’ leave of absence from September 11, 1913, with permission to go beyond the sea.

Currie, B. F., Acting Assistant Surgeon. Granted thirty days’ leave of absence from August 26, 1913.

Dox, Carroll, Surgeon. Granted twenty-one days’ leave of absence from September 2, 1913.

Gleannan, A. H., Assistant Surgeon. Granted nine days’ leave of absence from September 2, 1913.

Goldberger, Joseph, Surgeon. Granted one day’s leave of absence, August 22, 1913, under paragraph 195, Service Regulations.

Grubbs, S. B., Surgeon. Granted three days’ leave of absence from September 11, 1913, without pay.

Herring, R. A., Passed Assistant Surgeon. Granted twenty-one days’ leave of absence from September 23, 1913.

Horning, Henry, Acting Assistant Surgeon. Granted fourteen days’ leave of absence under paragraph 214, Service Regulations.

James, W. F., Acting Assistant Surgeon. Granted seven days’ leave of absence, from August 1, 1913, under paragraph 214, Service Regulations.

Magruder, G. M., Surgeon. Granted seven days’ leave of absence from September 1, 1913.

Markoe, W. W., Acting Assistant Surgeon. Granted ninety days’ leave of absence, without pay, from August 1, 1913.

Marsh, W. H., Acting Assistant Surgeon. Granted fourteen days’ leave of absence from September 12, 1913.

Mason, W. C., Acting Assistant Surgeon. Granted six days’ leave of absence, without pay, from September 14, 1913.

Nydegger, J. A., Surgeon. Granted one month’s leave of absence from September 1, 1913.

Scott, J. T., Acting Assistant Surgeon. Granted thirty days’ leave of absence from September 7, 1913.

Seidell, Atherton, Technical Assistant. Granted thirty days’ leave of absence, without pay, from September 1, 1913.

Storrs, Harry B., Acting Assistant Surgeon. Granted thirty days’ leave of absence from September 1, 1913.

White, M. J., Surgeon. Relieved from duty at Detroit, Mich., and directed to proceed to St. Louis, Mo., and assume charge of the Service at that port.

United States Army Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Department of the United States Army for the week ending September 13, 1913:

Cohn, W. T., Jr., First Lieutenant, Medical Corps. Left Presidio of San Francisco on August 30th on one month’s leave of absence. Chamberlain, W. P., Major, Medical Corps. Granted twenty-one days’ leave of absence, to take effect about September 12th.
arrival of another medical officer. Glennan, James D., Lieutenant Colonel, Medical Corps. In addition to other duties, ordered to report to the Commandant, Army Medical School, for assignment to duty as professor of medical department. Hoyt, E. F., First Lieutenant, Medical Reserve Corps. Relieved from observation and treatment at the Walter Reed General Hospital. Hardaway, Robert M., First Lieutenant, Medical Reserve Corps. Upon arrival in New York, N. Y., will proceed to Fort Yellowstone, Wyo., and report in person to the commanding officer of that post for duty, and by letter to the commanding general, Second Division, for assignment to duty. Reasoner, M. A., Captain, Medical Corps. Relieved from duty at the Signal Corps Aviation School, Spangdahlem, Germany, September 19th. Reynolds, Charles R., Major, Medical Corps. Relieved from duty at the Army Medical School as professor of duties of medical officers, medical department administration, and customs of the service. Roberts, Ernest E., First Lieutenant, Medical Reserve Corps. Upon arrival in the United States will proceed to Fort Caswell, North Carolina, and report in person to the commanding officer of that post for duty, and by letter to the commanding general, Second Division, for assignment to duty. Trinder, John H., Major, Medical Corps. Upon being relieved from duty at Fort Omaha, Neb., will proceed to Texas City, Texas, and report in person to the commanding general, Second Division, for assignment to duty. Wall, Francis M., First Lieutenant, Medical Reserve Corps. Upon his arrival in the United States will proceed to Fort Lawton, Wash., and report in person to the commanding officer of that post for duty, and by letter to the commanding general, Second Division, for assignment to duty. Watson, Charles M., First Lieutenant, Medical Corps. Is relieved from duty at Fort Douglas, Utah, and will proceed to Texas City, Texas, and report in person to the commanding general, Second Division, for assignment to duty. Whitcomb, C. C., Major, Medical Corps. Will proceed from New York city to Trenton, N. J., on a business pertaining to the Medical Department, and in connection of the Hospital of his proper station. Whitmore, Eugene R., Major, Medical Corps. So much of paragraph 23, Special Orders No. 189, August 14, 1913, as related to Major Whitmore is amended by substituting the proper hospital, pathology, and clinical diagnosis at the Army Medical School, instead of professor of military and tropical medicine.

The following named medical officers of the Medical Reserve Corps are relieved from duty at the stations designated, effective at such time as will enable them to comply with the order and repair to the Army Medical School, Washington, D. C., for the required course of instruction, reporting on or about September 20, 1913: First Lieutenant Charles A. M. Brown, Fort Howard, Md.; First Lieutenant Walter L. Colton, Fort Travis, Tex.; First Lieutenant John M. Pratt, Fort Ethan Allen, Vt.; First Lieutenant Robert H. Wilds, Fort Leavenworth, Kans.; First Lieutenant Frederick Thode, Fort Hamilton, N. Y.; First Lieutenant W. A. Wadsworth, N. Y.; First Lieutenant John B. Anderson, Fort Monroe, Va.; First Lieutenant William V. Vaughan, Fort Myer, Va.

**Deaths.**

**Comstock-Hynes.**—In New Haven, Conn., on Wednesday, September 30th, Dr. Frederick W. Comstock and Miss Edna E. Hynes. Hult-Munsel—In Detroit, Mich., on September 29th, Dr. Arnaud J. Hult and Miss Charlotte M. Munsel. La Pierre-Charter. — In Hartford, Conn., on Monday, September 28th, Dr. John A. Whitcomb and Miss Lillian H. Charter. Phillips-Scott.—In Lexington, Mass., on Tuesday, September 10th, Dr. William David Phillips, of New Orleans, La., and Miss Mary G. Scott. Pinto-Lazure. — In St. Louis, Mo., on Friday, September 4th, Dr. Walter A. Pinto and Miss Rosemary Lazure.

**Married.**

**Barr.**—In Eufaula, Ala., on Monday, September 30th, Dr. James M. Barr, aged eighty years. Blaine.—In Carnegie, Pa., on Sunday, August 31st, Dr. James Milton Blaine, aged eighty-five years. Broughton.—In Greenville, Ala., on Friday, August 29th, Dr. John Thomas Broughton. Brown.—In Fort Valley, Ga., on Tuesday, September 29th, D. H. A. Brown. Catts.—In Alexander, Va., on Friday, August 29th, Dr. Samuel R. Catts, aged thirty-five years. Cordell.—In Baltimore, Md., on Wednesday, August 27th, Dr. Eugene F. Cordell, aged seventy years. Corson.—In Norristown, Pa., on Sunday, September 7th, Dr. Elwood Naubly Corson, aged seventy years. Currie.—In Morganton, N. C., on Wednesday, September 30th, Dr. Walter B. Currie, aged seventy-nine years. Fleming.—In Mount Vernon, N. Y., on Tuesday, September 9th, Dr. Walter Miller Fleming, aged seventy-five years. Frey.—In Beaumont, Texas, on Sunday, September 7th, Major H. Frey, aged forty-eight years. Harrison.—In Memphis, Tenn., on Monday, September 8th, Dr. W. K. Harrison, aged seventy-two years. Hetrick.—In Wellsville, Pa., on Thursday, September 4th, Dr. Augustus Christian Hetrick, aged seventy-eight years. Howard.—In Worces- ter, Mass., on Monday, September 8th, Dr. Eugene Howard, aged seventy-two years. Laws.—In Haddonfield, N. J., on Sunday, September 7th, Dr. John H. Laws, aged sixty-seven years. McFadden.—In West Pittston, Pa., on Thursday, September 4th, Dr. Charles Joseph McFadden, aged forty-five years. Mueller.—In Chica- go, Ill., on Thursday, September 3rd, Dr. William A. Mueller, aged forty-eight years. Patton.—In Montreal, Que., on Friday, September 5th, Dr. Hugh Matthewson Patton, aged forty-eight years. Taplin.—In Rochester, N. Y., on Tuesday, September 9th, Dr. Horace A. Taplin, aged sixty-six years. Van Santvoord.—In New York, on Wednesday, September 10th, Dr. Richard Van Santvoord, aged fifty-five years. Wagenseller.—In Schenksville, Pa., on Thursday, September 4th, Dr. Frank J. Wagenseller, aged sixty years. Webb.—In Detroit, Mich., on Wednesday, September 3rd, Dr. Lucien F. Webb, aged thirty-five years. Whitten.—In Nebraska City, Neb., on Friday, September 5th, Dr. Elisha M. Whitten, aged seventy-six years.
PUBLIC EDUCATION IN CANCER.*

BY WILLY MEYER, M.D.,

New York,

Attending Surgeon to the German and Postgraduate Hospitals.

In approaching the subject of public education in cancer from the surgical point of view three important questions present themselves, namely: 1. What is the cause of cancer? 2. Is cancer contagious or infectious? 3. Can cancer be cured by operation? These questions are almost invariably put to the doctor when consulted by patients suffering from cancer.

1.—WHAT IS THE CAUSE OF CANCER?

This is hardly the proper time nor perhaps the place to ventilate this all absorbing question, and yet it seems to me that it has quite some bearing on public education.

It is a fact that the views of pathologists and surgeons do not agree on this point; the former rather lean toward Ribbert's theory, viz., "that a cancerous tumor is incited by a disturbance of the physiology of the epithelium which is due to cellular changes in the supporting connective tissue (proliferation of subepithelial fibroblasts), the latter producing new tissue and disturbing the tension between epithelium and connective tissue." whereas surgeons, as a rule, judging from clinical observation, feel convinced that the cause of carcinoma must be a living organism. Let us take, for instance, a tumor of the breast which does not show the clear signs of carcinoma. We shall usually find that the differential diagnosis rests between malignant tumor, tuberculosis, syphilis, or actinomycosis. Now, we know that tuberculosis is caused by the tubercle bacillus, syphilis by the spirochete, actinomycosis by the Actinomyces bovis. Does it not almost seem logical, then, to assume that a tumor which closely simulates that produced by any one of these diseases, the microbic or parasitic cause of which is known, should have a similar origin if found to be a malignant growth? Furthermore, how could we explain the interesting observation, made in some suburb of London in a damp tenement house, that quite a number of members of different families who moved into this house one after the other were stricken down with cancer? And these observations can be multiplied.

Personally I decidedly lean toward the theory that a living organism is the cause of carcinoma. 6

Permit me to just cite a few personal experiences bearing upon this point:

In the early nineties when there was much discussion regarding the question of injecting methyl violet, in cases of inoperable carcinoma, according to the method of von Mosetig-Moorhof, of Vienna, I once injected a female patient with fuchsin solution for an inoperable regional recurrence after a radical operation for cancer of the breast. It was done at my office in the usual way, the needle being pushed into the infiltrated area. She was to present herself three days later. But on the day following the injection she came back—it was in summer time—complaining of a peculiar itching sensation in the region of the injection. On exposing the field, I beheld a picture which absolutely resembled acute eczema. There were innumerable mililiary elevations in the area where the injection had been made, clearly defined by an irregular border line. I explained to the patient that we had to deal with an acute eczema, as it not infrequently occurs when dressings cover the skin in summer, and treated her accordingly. However, I was surprised to notice, in the course of further observation, that the symptoms which had so suddenly set in were not due to acute eczema, but to a localized mililiary carcinosis; each of the small nodules developed into a distinct carcinomatosus infiltration.

This observation can hardly be explained in any other way than to assume that by means of the injection a cancerous nidus was invaded and that now, through one of the smaller arteries, embolism were carried into the field, fed by this vessel. On the basis of comparison, especially with mililiary tuberculosis, is it not plausible to assume that a supposed living organism, and not cells, produced these emboli and then the visible swelling within twenty-four hours? Is it possible that within one day these cells should have been multiplied to the extent of producing a visible tumor?

I would cite another instance: Not long ago I was called upon to operate upon a patient apparently suffering from peritoneal tuberculosis; all clinical signs were well developed. On opening the abdomen the usual picture was found, except that the

*This belief has become almost conviction, since I have seen, at the scientific exhibit of the American Medical Association in Minneapolis this summer, the wonderful specimens and photographs of plant cancer shown by Dr. Erwin F. Smith, of Washington, D. C. I am sure the majority of those who have been fortunate enough to view the tangible results of the labors of this persistent research worker will have gone away with the impression that since carcinoma has been experimentally produced in plants by injecting a cultivable microbe, the same very likely will be found to be the case in man. (Footnote made at time of correcting proof.)

Elliott Publishing Company.
nodules were a little more pronounced than generally seen in these cases. A piece of omentum was removed for microscopical examination which latter proved that we had to deal with tuberculous carcinoma. I am sure, had I made special attempts to palpate the abdominal organs, I should have found the primary seat of the trouble.

Now, if the tubercle bacillus produces a picture almost identical to that seen in tuberculous carcinoma, is it plausible that the latter should depend on entirely different origin?4

However, it is not only the surgeons who are generally found to believe in the parasitic or microbic origin of cancer. I was greatly interested in the recent report of Professor Kleper, director of the Moabit Hospital and of the Institut für Krebsforschung in Berlin, read last year before the meeting of the General Committee for the Study of Carcinoma in Germany, in which he stated his belief that carcinoma was most probably due to a living organism (belebter Erreger). He adds "Let us continue our search and we shall find it."

Now it might be asked, What has all this to do with the public education in cancer? Very much indeed! The public must understand that real progress in the treatment of carcinoma cannot be made until the true cause of the disease has been found. Just think of the immense progress that has been made in the treatment of syphilis since the spirochetes could be reproduced in cultures,—since animal experimentation could be added to help us solve the vexed problems. The same will occur with carcinoma.

But for this purpose money is needed, plenty of money, rich endowments for cancer research institutes and others working along these lines. Well was it said by Professor Czerny, when he exclaimed at a recent discussion: "If England and Germany could but make up their mind to build one dreadnought less in a single year and the ten million dollars thereby made available in each country were given to science to be used for research work in cancer, what an amount of good could be accomplished!" Let us hope that the "Schau-dinn" for finding the cause of carcinoma has been born, nay, that he is already a grown man and scientist among us, who may come forward any moment to demonstrate his discovery!

2.—IS CANCER CONTAGIOUS?

The public asks this question right along, and we can conscientiously answer the question in the negative. Never has it been observed that a faithful wife, assisting the husband in attending a sick husband for months and years, has become infected with the same trouble; never has it been reported that a surgeon prickling himself in the course of an operation for carcinoma was attacked with the disease. And yet this has occurred following an injury received during an operation for tuberculosis. Evidently transmission must go on in carcinoma in a different way from individual to individual. Personally, I have made but one observation which might be said to have some bearing on this question.

Years ago I removed from a male patient a papilloma of the bladder almost as large as an apple; its base was pedunculated; traces of carcinoma were found in its base. In the course of the following years, multiple tumors appeared which were evidently carcinomata, clearly discernible with the cystoscope, and located within his bladder and on the surface of the prostate. The bladder was reopened and the tumors removed. He lived for nearly two years more, and then died of a recurrent, inoperable, vesical carcinoma. In the course of the last year of his life I was called to examine his wife, who then showed unmistakable symptoms of a cancer of the cervix uteri. Whether this was interdependent or coincident, I should not venture to decide. I also cannot state whether the same microscopic type of carcinoma was found in both patients.

3.—CAN CANCER BE CURED BY OPERATION?

This question we can answer with a decided "yes," provided the patients come to us in the early stage of the disease. We must distinguish three stages of development in cancer: 1. Localized disease; 2, plus involvement of the regional lymphatic glands; and 3, the same, with metastases. Experience has shown that the first two stages are amenable to cure by operation. Observations throughout the world confirm this as regards cancer of the breast, uterus, gastrointestinal tract, kidney, etc. Everywhere it has been proved that from thirty to fifty per cent. of patients, subjected to a radical operation for carcinoma of the breast, even with involvement of the glands in the axilla and along the subclavian vein, have passed the three or five year limit. Wertheim, of Vienna, has shown by his excellent statistics covering 500 cases of cancer of the uterus, operated in by his radical method, that fully forty-two per cent. have been cured. Kocher proved that twenty per cent. of his patients treated by resection of the stomach remained permanently free from recurrence. Kraska, of Freiburg, reports similarly good results from operation in cases of cancer of the rectum, etc. And just think in what an advanced stage these patients, not infrequently, reach the surgeon. How many men could have been saved, had they come to operation at an earlier period. Hence, the watchword is, and always will be: Early operation! But early operation depends on early diagnosis. To make both possible, I think special courses should be given in our colleges on the early symptoms of cancer. It is necessary, first, to educate the profession itself on this most important question, although it is undoubtedly true that in many instances the family physician is not to blame if his patients reach the surgeon at a late period of the disease. It is the patients themselves who often do not consult their physician, until a malignant stricture of the esophagus, colon, or rectum has become fully developed and the glands are so extensively involved, that even with the most radical operation it is impossible to guarantee that every vestige of the disease has been excised.

But, if they do come to the family physician in time, he should be able to recognize at once whether there is any suspicion of carcinoma.
One of the principal symptoms of cancer in the genitourinary system as well as in the gastrointestinal tract is blood in the vaginal discharge, in the urine, or in the stool. Gradually it has been recognized by the profession that blood in the urine is a most important clinical symptom, and that it is the physician's duty to find the cause of the hemorrhage. Special emphasis has to be laid on the importance of the so-called symptomless hematuria. We know that the cases of cancer of the kidney, in which hemorrhage occurs and diffusely colored urine is discharged, without pain to the patient, are the ones in which death so frequently means certain death. The same holds good in connection with cancer of the rectum. Patients are only too ready to explain the bloody discharge from the rectum as being due to the presence of hemorrhoids; but how often does the busy physician give the same answer and never think of the necessity of introducing the finger into the rectum, or of insisting upon a thorough rectoscopy. The same is true of blood discharges from the vagina, especially after the menopause has set in.

To-day the electric lamp has literally carried a bright light into these hitherto dark fields of surgery. We are able to view the bladder and can have the patient come during the time of the hematuria for visual examination. We are able to push the sigmoidoscope up into the intestine for many inches and are able to see and perhaps trace the source of the bleeding. We have the esophagoscope to examine the tube from the pharynx down to the cardia, if the patient complains of difficulty in swallowing.

The latter class of patients usually come to the doctor early, as they become frightened in view of the daily recurrence of the same trouble. They present themselves stating that without any warning or cause known to them, they noticed that the food would not descend to the stomach in the usual way. This is the time that the physician should insist upon a most careful examination. Examining with special esophageal sounds, fluoroscopy, radiography in a special way, and esophagoscope will, in most cases, enable us to make an early diagnosis. And if doubt still remains, we have learned that exploratory thoracotomy nowadays is as safe as exploratory laparotomy. If, on opening the chest, the findings should verify the suspicion, the surgeon should be prepared to do radical work. Let us remember that cancer of the esophagus is the most benign of all malignant growths in the gastrointestinal tract! Let the physician further bear in mind that it has been proved that in eighty per cent. of the cases with slowly increasing difficulty in deglutition, cancer is at the bottom of the trouble.

And now as to the public. There is no question that it is in need of education along these lines. Our female patients have to know that a tumor of the breast, though it be of but slow growth and never occasions any pain, is nevertheless most dangerous. How many times have we heard the statement from our patients, "Well, it did not hurt me, so I waited, because I thought that the tumor was of no importance." The public must be taught the clinical truth; they must learn that every tumor is a surgical disease. The public must be taught that in the event of a rather rapid onset of so-called indigestion which remains unrelieved, despite everything the physician may have tried, and in the absence of tenderness over gallbladder and appendicular region, the possibility of the presence of a cancer of the stomach must be considered. They themselves should be educated to the point of insisting upon an examination under anesthesia, or, if that, too, should still leave doubt, on an exploratory laparotomy. This certainly is no plum desideratum. Think what they have learned in regard to appendicitis. How they come to us today with the statement: "Doctor, I had a pain in the right side of my abdomen; it also hurt me on pressure. I hear from my friends that this is a sign of appendicitis. Please examine me and, if necessary, remove the appendix." This is the goal we have been working for as regards this treacherous disease for many years. How many lives are saved nowadays by the proper recognition of the dangers of appendicitis by the public at large.

At this moment it is scarcely necessary to discuss the question of how the public should be instructed. The ball, fortunately, has been started. We all know of the general publicity campaign that has been taken up by the Cancer Campaign Committee of the Congress of Surgeons of North America. We know that the New York Committee was formed with the support of wealthy people who have made it their business to promulgate among the public the truth regarding malignant disease. The way along which they have advanced is the correct one. Articles should appear in our weekly or monthly journals, and from these they should be copied in the daily press. It certainly was of greatest interest to me the other day at Washington at the Congress of American Physicians and Surgeons, to listen to the remarks of Dr. Thomas S. Cullen, of Baltimore, regarding the education of the people as to what can be done in early cases of cancer. He showed by letters received from various patients and physicians, how the excellent article lately written in the May issue of McClure's Magazine by Mr. Samuel Hopkins Adams had brought a tremendous amount of good in its wake. Quite a number of patients who had been hesitating about submitting to operation were induced by the husband, or the husband by the wife, to consult a surgeon and be guided by his advice. That is the way to advance. According to our laws of medical ethics, it would be improper for a physician to write an article himself for publication in the magazines or daily papers. Laymen have to address the laity. They know much better how to put the matter in proper shape to be understood by the masses, and there seems to be no man better fitted for this purpose than Mr. Adams.

Let us hope, then, that this public education, which has just commenced, will go on. Let us hope that public education in questions of carcinoma will bear the same good fruit, as that resulting from enlightening the public concerning questions of tuberculosis, and more recently also of syphilis, in order that many lives otherwise utterly and sadly lost will be saved.

700 Madison Avenue.
PULMONARY SYphilIS.

With Report of a Case Promptly Responding to Specific Treatment.*

By Albert E. Roussel, M. D.,
Philadelphia.

Associate Professor of Practice and Clinical Medicine, Medico-Chirurgical College; Visiting Physician to the Medico-Chirurgical and to the Howard Hospitals; Officier de l'Academie francaise; etc.

Pulmonary syphilis, excepting the congenital form in children, is a rare disease and it is worthy of attention that, since the recognition of tuberculosis as a cause of phthisis, few cases have been reported and with the now accurate tests for syphilis the cases will be still fewer and the diagnosis accurate.

Carlier, in 1882, collected seventy-five cases with fifty autopsies. Hiller, in 1884, reported eighty-seven cases, eighty-four of these with autopsies (twenty had been previously reported by Carlier).

Fowler, after an examination of the museums of the London hospitals and the Royal College of Surgeons, found twelve specimens which illustrate syphilitic lesions of the lungs (not congenital).

Conner, in an analysis of 120 cases of syphilitic stenosis of the bronchi, etc., reports the autopsies in fifty-six cases. In ten cases (18 per cent.) lesions believed to be characteristic of syphilis of the lungs were found. In all these excepting one there existed chronic interstitial pneumonia of greater or less extent. In two cases distinct gumma was found. Evidence of tuberculosis in three cases. In nineteen cases pneumonia, more or less extensive, in seven lobar pneumonia, and in twelve either lobular pneumonia or bronchopneumonia.

Bronchial catarrh may occur as a manifestation of the secondary stage of syphilis and be alleviated or cured by specific treatment. In the late secondary or tertiary stage gummatous infiltration of the submucous tissue of the trachea and bronchi is not infrequent, with resulting stenosis of the parts. Pulmonary lesions of acquired syphilis belong chiefly to the tertiary stage (two to twenty years).1

Gumma may occur singly or in numbers in size from a hempseed to a goose egg, and are more commonly found in the interior of the lung and more often in the lower lobes than the upper, thus differing from the seat of election of tubercle.

According to Councilman, who reports two cases with autopsies, the essential process in the production of a gumma in the lung is a pneumonia with fibrous exudation, accompanied by fibrous changes on the alveolar wall, the whole subsequently undergoing caseation. Hewop reports a case, with a description of the anatomical changes and a plate. In his case there were numerous gummatas in both lungs from the size of a beet to that of a goose egg without any breaking down of tissue.

Lobular Pneumonia or Bronchopneumonia.—There is but little doubt that many of the cases of this type reported in the past, before the tubercle bacillus was recognized, were probably tuberculosis, but Fowler describes a specimen in St. George Hospital where such a possibility can be excluded, and the more recent reports of Conner already quoted and others prove its occurrence.

Fibroid Induration.—The following are the more important changes of this nature which have been attributed to syphilis: Thickening extending from the hilus around the bronchi and vessels; isolated masses of fibroid tissue in various parts of the lung; diffuse changes occupying the whole or the greater part of the lung.

A Progressive Destructive Disease—the so Called Syphilitic Phthisis. — Pancherius (Berlin, 1881) (quoted by Councilman) makes the astounding statement of syphilitic phthisis, as one of the most frequent diseases—one that decimates the flower of the land. Fowler, from whom I quote extensively, reports five cases, one of whom improved, and four autopsies. He makes the following qualifications:

First, the case must be complete, that is the symptoms observed during life must be considered in connection with the lesions discovered at post mortem examination;

Second, the evidence of syphilitic infection must be undeniable;

Third, repeated examination of the sputum must have been made and tubercle bacilli have been invariably absent;

Fourth, syphilitic lesions about the nature of which there can be no doubt must be found in other organs;

He draws attention to the chief points of difference between the pulmonary lesion of tuberculosis and of syphilis.

First, tubercle usually affects the apex of the lung, subsequently the apex of the lower lobe. The lesion of syphilis is often about the root and central portion of the lung and follows no definite line of march;

Second, both tubercle and gumma may undergo either necrosis and caseation or fibrous transformation, but with caseous tubercle the tendency toward softening and cavity formation is the rule, whereas a caseous gumma rarely breaks down;

Third, cavities are common in tuberculosis and are rare in syphilis, excepting secondary to stenosis of the main bronchi;

Fourth, stenosis of the trachea and main bronchi are common in the advanced stages of syphilis, rare in tuberculosis;

Fifth, cavities in pulmonary syphilis are generally but not invariably bronchietasis, and in tuberculosis they are due to destruction of the lung tissue;

Sixth, the tendency to the formation of pulmonary aneurysms, which is so marked a feature in tuberculosis, is rarely observed in pulmonary syphilis;

Seventh, pulmonary lesions in tuberculosis are very common, whereas in syphilis they are extremely rare.

Howard Hospital. Case 9469. Admitted January 31, 1913. Discharged as cured April 1, 1913. Female, colored, single. Aged twenty-four years, normal weight 135 pounds, now 115 pounds. Family history was good with a total absence of tuberculosis. Subsequently (six weeks later), in the personal history, we ascertained that five years ago there was a distinct history of syphilitic infection...

*Read before the American Therapeutic Society at Washington, D. C., May 6, 1911.

1It is interesting to note that tertiary lesions may occur much earlier. The author reported a case of gummatous ulceration of the hard palate, ten weeks after the appearance of the chancre. A Case of Malignant Syphilis Resulting in Death, Medical News. May 20, 1893.
and sequela, and no less than five miscarriages. The previous medical history was otherwise negative. Chills, fever, sweating, cough, expectoration, marked loss of twenty pounds in weight. About six weeks before admission to the hospital the patient complained of chilly feeling, fever, and cough, and was on respiration taken to be 106°F and over, and on occasions, in the course of several hours, would reach as low as 66.2°F. The sweating was very profuse, so much so that the night dress and sheets were constantly saturated. On examination of the patient there was found an incised, contused wound of the scalp, about one and one half inches in length, in the right parietal region. After cleansing the wound it was found to extend down to the bone, and a few drops of serum were expressed.

Dr. Edward Martin examined the wound and pronounced it of no importance, and not connected with the symptoms.

Eyes.—Pupils reacted sluggishly to light and accommodation. The patel. reflex was also sluggish. There was an absence of the Babinski reflex, the ankle-clonus, Kernig's sign, and the sacrum reflex. The patient showed no increase in weight. Three days after the admission there was noted an expression of the left eye which led to the possibility of weight loss. Three days later she was hit on the head in right parietal region with a brick. The wound was treated and looked healthy on admission. Since that time all these symptoms became more marked—severe chills followed by fever, with abundant expectoration. On examination of the patient there was found an incised, contused wound of the scalp, about one and one half inches in length, in the right parietal region. After cleansing the wound it was found to extend down to the bone, and a few drops of serum were expressed.

pyrexia is present when there are extensive lesions; this may be considerable and of the hectic type. Diagnosis, look for lesions of the calvarium, sternum, and ribs.

The prognosis is grave, but cases are on record of improvement and cure. Areas of pneumonia consolidation may be overlooked because of the absence of bronchial breathing where stricture of the bronchi exist; gummatas and ulcers in most cases readily respond to antisyphilitic treatment. At the present day we will add to the diagnostic signs the Wassermann reaction, and if possible, the finding of Treponema pallidum.

Thanks are due to the particular care and interest exhibited in the case by Dr. John L. Groh, my interne at the Howard Hospital.

EUGENICS AND THE PUBLIC HEALTH.

By C. P. Wertenbaker, M. D.,
Norfolk, Virginia,
Surgeon, United States Public Health Service.

The science of eugenics being comparatively new, and information of its relations to the public health not being easily obtainable, an effort has been made here to give a brief outline of the subject, with a statement of the measures proposed to meet the conditions they are intended to correct.

The rapid increase in the number of feebleminded and otherwise defective in this country has now reached such proportions, as to attract the earnest consideration of thoughtful people who have the welfare of the nation at heart. Grave as the situation is, even with our present knowledge of it, all the facts are not fully known. The inadequacy of records on the subject, and in many parts of the country their total absence, makes it impossible to do more than form an approximate idea of the number of feebleminded, diseased, and otherwise defective in the United States. There are vast sections of the country, especially the rural districts, of which we have practically no statistical information as to the prevalence of disease, or feeblemindedness or the social and industrial conditions under which the people live. The facts presented here have been gathered from many scattered sources, and it has not been possible to give credit for them in all cases, though an effort has been made to do so. Attention is invited to the bibliography attached, to which the reader is referred for more detailed information on the subjects.

Eugenics is defined by Sir Francis Galton, who suggested the term in 1883, as “the study of the agencies under social control that may improve or impair the racial qualities of future generations, either mentally or physically.” It has also been called race hygiene. The word “eugenics” is derived from the Greek word, “good birth.” President David Starr Jordan, of Leland Stanford, Jr., University, in his Heredity of Richard Roe (1911) calls it “the science and art of being born well.” Though the science of eugenics is comparatively new, the idea itself is very old. As far back as history reaches the general principles of eugenics have been known, and the mating of selected animals in order to improve the strain has long been practised. The value of “good blood” in man has long been recognized, and much importance is attached to the strain from which an individual comes. “Blood will tell” is a common phrase that recognizes the fact that inheritance plays a most important role in determining the characters of an individual.

In 1800-65, Gregor Johann Mendel, an Augustinian monk, who was a teacher of natural sciences in the monastic school at Brunn, Moravia, in Austria, experimented in raising garden peas in the yard of the monastery. He noted certain characters of the peas that he raised, such as their shape and color; the color of the leaves; the shape of the seedpod; the nature of the flowering; length of the stem, etc. He also experimented in crossing peas having different characters, and learned some very interesting facts that have important bearing on the science of eugenics. He found in every case that the offspring of the cross exhibited the character of one of the parents. Intermediate forms, not evidently leaning to one parent or the other, were not found. These traits are considered unit characters, inherited without division or blending. In each pair of contrasted characters one prevails in each individual of the progeny. The trait that thus prevails was called by Mendel the “dominant” character, the other being called the “recessive” character.

By allowing the crossbred peas to fertilize themselves, Mendel reared another generation in which there were individuals which showed the dominant character, but also individuals which presented the recessive character. This fact has been noted before, but Mendel noticed that in this generation the numerical proportion of dominants to recessives is almost constant, being as three to one. In the first generation raised from the crossbreds there were seventy-five per cent. dominants and twenty-five per cent. recessives. These plants were again self fertilized, and the offspring of each plant separately sown. It next appeared that the offspring of the recessives remained pure recessives, and in subsequent generations never produced the dominant again. When the seeds obtained by self fertilizing the dominants were examined and sown, it was found the dominants were not all alike, but consisted of two classes, viz.: 1. Those that gave rise to pure dominants. 2. Others which gave a mixed offspring composed partly of recessives and partly of dominants. Here also it was found that the average numerical proportions were constant, those with pure dominant offspring being to those of mixed offspring as one to two. The process of breaking up into the parent forms is thus continued in each successive generation, the same numerical law being followed so far as observed.

Mendel published his paper in 1805, but it was not until 1900, when several observers rediscovered the same facts, that due recognition was given to their importance in the study of heredity. Since that time much work has been done upon the subject confirmatory of the Mendelian law. The discovery of this law gives an explanation of many characteristics of inheritance that had been observed but were not understood. It makes clear how atavism.
or reversion to type, may occur, in which the characters of a remote or collateral ancestor may appear in an offspring after skipping one or more generations. It appears that each individual is supplied with certain germ cells derived from the parents, who in turn received them from their parents, etc. These represent the characters of the individual, and variations may be explained by the Mendelian law.

C. B. Davenport, who has made special studies of the inheritance of blue and brown eyes in man, found that when two brown eyed people mate only brown eyed offspring result. When one parent is brown eyed and one blue eyed, one half the offspring will be blue eyed, and of their children one in every four will be blue eyed. This law holds good for many other physical characteristics.

Speaking of this subject, H. E. Jordan, of the University of Virginia, in his paper Eugenics: The Rearing of the Human Thoroughbred, says: "There prevails a justifiable presumption that the same principle governs also the transmission of physical and pathological characters. The point is that what is in the germ cell will come out at some time, and in a certain definite proportion, according to the type of the mating. If we want sound men, strong men, intelligent men, temperate men, chaste men, wise men, they must be bred from their type." That this is true is proved by numerous instances in which the histories of certain families have been traced through several generations. It has been conclusively shown that good stock brings forth good offspring, and degenerate stock brings forth defective offspring. It has also been shown in the mating of a normal person with a defective, that the degenerate influence persists through several generations.

In this connection the history of Martin Kallikak is most interesting. The name Kallikak is fictitious, as might be supposed, but the history is true. Dr. Henry Herbert Goddard, director of the Research Laboratory of the Training School for Feebleminded Boys and Girls at Vineland, New Jersey, in tracing the family history of one of the inmates of that institution whom he calls Debora Kallikak, worked out this history. During the American Revolution Martin Kallikak, a young man of good family, joined a militia company, and while stopping at an inn frequented by the military, he became the father of a feebleminded son by a feebleminded girl employed at the inn. From the line thus started there came 480 descendants; 143 of these have been feebleminded; only forty-six have been normal; thirteen were illegitimate; thirty-three were sexually immoral, mostly prostitutes; twenty-four were confirmed alcoholics; three were epileptics; eighty-two died in infancy; three were criminals; eight kept houses of ill fame; and the rest are unknown or doubtful. These people have married into other families, generally of the same type, so that there are now on record and charted 1,146 individuals of whom 262 are feebleminded; 197 considered normal; and 581 still undetermined.

On leaving the revolutionary army Martin Kallikak married a respectable girl of good family, and through that union there has come a line of descendants of radically different character. These number 496, all of them normal people. Three men only have been found among them who were somewhat degenerate, but not defective. All of the children of Martin Kallikak of this line married into the best families of the State, and have been good citizens. There have been no feebleminded among them; no illegitimate children; no epileptics or criminals; no immoral women. Only fifteen children have died in infancy. The contrast between the two lines of descendants is most strongly marked. From the feebleminded mother came a long line of feebleminded, degenerates, and criminals, while with the same father and a normal mother there is a line of good citizens who have taken high places in society, and contributed to the welfare of the state.

The Juke family, reported by Dugdale, consisted of five daughters of a lazy irresponsible fisherman, born in 1720. In five generations the family increased to about 1,200. The histories of about 1,000 are known; there were among them 310 professional paupers in almshouses for a total of 2,300 years; 440 were syphilis; more than half of the women were prostitutes; 130 were convicted criminals; sixty were habitual thieves; seven were murderers. This family has cost the State over a million and a quarter dollars.

Poellman gives the history of a family established by the two daughters of a woman drunkard who in six generations produced 834 descendants. The histories of 700 are known: 107 were of illegitimate birth; sixty-four were inmates of almshouses; 162 were professional beggars; 164 were prostitutes, and seventeen were procurers; seventy-six had prison sentences that aggregate 116 years; seven were murderers. This family has cost the State more than a million dollars and is still prolific.

In contrast with the foregoing, the history of the Edwards family shows that a good tree brings forth good fruit. Jonathan Edwards, of Connecticut, had 1,900 descendants, the histories of 1,394 being known. Among them there have been: Thirteen college presidents; sixty-five college professors; 295 college graduates; sixty physicians; 100 clergymen of renown; seventy-five officers of the army and navy; sixty prominent authors; 100 lawyers; thirty judges; eighty who held public offices; three United States Senators; fifteen prominent in railroad work, banks, insurance companies, and business.

These facts have an important bearing upon the public health. It is well known that an individual with an enfeebled physique from any cause is more liable to contract disease than one who is strong and healthy. It has also been repeatedly shown that parents who are not healthy do not have strong and healthy children. It is also probable that a tendency to certain diseases is inherited. This is evidenced by the fact that cancer, tuberculosis, diseases of the heart, kidney, etc., frequently make their appearance in succeeding generations of the same family. We know that certain physical peculiarities, such as extra fingers or toes, a peculiar birthmark, or strong family resemblance may be transmitted from parent to offspring through several generations. It is as though Nature had contracted a habit of reproducing these characters. If physical characteristics such as these can be
transmitted, there seems to be no reason why resistance to certain diseases, or the lack of it, should not also be inherited. This accords with experience along these lines, for it is not infrequently found that children are markedly susceptible to the same diseases to which one or both parents have shown susceptibility. This is also true of immunity to certain diseases.

The inheritance of mental and moral characteristics is so well known that the common expression “a chip from the old block” is used to convey the idea that the child is a replica of the parent. Neurologists tell us that the cure for that most distressing malady known as “sick headache” must commence with our great grand parents. That sufferers from this malady have inherited, through several generations, the nervous tendency that now finds expression in “sick headache.” No doubt this is true of many other ailments, and as our knowledge increases, it is possible that we will find that inheritance plays an important rôle in many diseases not now suspected.

The mental and moral characteristics of an individual are quite as important from a public health standpoint, as physical weakness or strength. The quality of the mind is often the factor that determines an individual’s position in life, and exercises a marked influence upon his health and well being. Upon that attribute of the mind known as judgment—the power to estimate facts at their true values—largely depends success or failure. It is the lack of this faculty, as much as any one thing, that is responsible for much of the poverty and sickness that exist. The deficiency of mind that leads to poverty also plays an important rôle in disease. The incapacity to appreciate the necessity for preventive measures in the preservation of health, as well as the inability to carry out such measures, is a factor whose importance in public health work has not been sufficiently appreciated in the past. While it is well known that poverty and disease frequently go hand in hand, it has not been fully appreciated that mental deficiency is often a common factor in both. It is not meant to say that poverty is necessarily a sign of lack of intelligence, for such a statement would be absurd, or that wealth means mental power, which would be equally absurd, but it is unquestionably true that unintelligence and poverty are often associated, and it is the lack of capacity due to inheritance that is often responsible for these conditions.

It is not alone in those who are classed as feebleminded that the degenerate influence is manifest. The fact is, we note those whose deficiencies are most marked, just as we recognize those with exceptional brain power, but between these two extremes is the great mass of the population whose mental capabilities are as varied as the individuals who possess them. No two are alike, and in their gradations they extend from brilliance and power on the one hand to feeblemindedness and idiocy on the other, and the differences are those of degree rather than of kind. The point it is sought to bring out is this: There are vast numbers of so-called normal people whose brain capacity is so low that they are capable of but a limited degree of mental development; that much poverty and ill health are results of this incapacity, and such incapacity may often be traced to degenerate influence in heredity. Just how far this degenerate influence may extend is not known, but it is evident that it does not stop with those who are classed as feebleminded, but must extend in a greater or lesser degree to all of the progeny. The histories of the Kallikak, Juke, and other families, show that the degenerate influence persists through generations. These are but isolated instances of what must be going on to a greater or lesser extent in many families, and its influence on the mentality of the nation must be profound. Like decay in a tree, commencing at or near its roots, and extending through the trunk and limbs, it finally affects the higher branches and the tree dies. In like manner the degenerate influence is spreading through the nation, blighting mind and body, and leaving in its trail poverty, disease, suffering, and death. Unless checked, it must ultimately lower the mental and physical standard of the nation. It is stated that the feebleminded are increasing at twice the rate of the rest of the population. If this ratio were to continue it would be only a question of time when there would be more feebleminded than normal people in the country.

It is not proposed to discuss here the relative influence of heredity and environment upon the human race. Let it suffice to say that heredity determines the quality of the clay, while environment often shapes the vessel. We seem to be composites of our ancestors, plus environment and training.

Edwin Markham in his poem, The Man with the Hoe, which was inspired by Millet’s painting of that name, says:

“Bowed by the weight of centuries he leans
Upon his hoe and gazes on the ground,
The emptiness of ages in his face
And on his back the burden of the world.
Who made him dead to rapture and despair,
A thing that grieves not and that never hopes.
Stolid and stunned, a brother to the Ox?
Who loosened and let down this brutal jaw?
Whose was the hand that slanted back this brow?
Whose breath blew out the light within this brain?”

Markham attributes the condition typified by the hoeman to industrial oppression, and considers him a degenerate through hopeless drudgery and barren environment. Is it not more probable that the hoeman’s condition is primarily due to the fact that he inherited a brain incapable of higher development, and that his condition is due to incapacity rather than industrial oppression and lack of opportunity? May it not have been some degenerate, syphilitic, or alcoholic ancestor who is responsible for his being “stolid and stunned, a brother to the Ox”? Had this man inherited capabilities for higher things would he not have risen above his hopeless drudgery and barren environment? It has been said, “If oppression comes it is because the opportunity is offered. It is not the strength of the strong but the weakness of the weak that engenders exploitation and tyranny.” However, whatever the cause of his condition, heredity or environment, the hoeman is with us by tens, and by hundreds of thousands, with his inability to combat with the circumstances in which he is placed.
It is he who fills our asylums, jails, and almshouses; who offers a fertile field for the propagation and dissemination of disease from which he is unable, mentally or financially, to protect himself. He is also with us with his ability to multiply himself by the propagation of children, and thus perpetuate the malignant influence which blighted his life. That he will do this is more than probable, for the lower the grade of the mind, the more strong the animal instincts appear to become.

It is in connection with such facts as these that the question of heredity touches and becomes amalgamated with the public health, and it is here-in that eugenics, in its efforts to correct these conditions, becomes a part of public health work. We are beginning to realize that the scope of public health work is broader than we thought. While sanitation, control of disease, and preventive medicine have lost none of their importance, and in these fields there are vast territories that are as yet but little explored, we now know that there are many other important factors that are embraced in the term "public health." To check the progress of disease in its full flood, is like attempting to sweep back the sea with a broom. It is necessary to check the flow at its source, to purify the fountain, in order to stop the flood of disease, degeneracy, and death. The public health official is therefore broadening his outlook, and is seeking for all the causes that influence, for good or evil, the health of the people. He realizes that it is necessary to be a sociologist, eugenist, etc., as well as a sanitarian, hygienist, and epidemiologist; that he must study the social, industrial, and hereditary conditions that affect mankind, if he would make the greatest progress in uplifting the public health.

The Aims of Eugenics.—What is sought to be accomplished by eugenics may be broadly stated as the improvement of the race by checking the propagation of defectives, and encouraging the mating of the most fit. There seems to be some misconception as to the aims of eugenics. Eugenists do not desire to eliminate sentiment, nor expect that the mating of human beings will be in accordance with a scientific formula, wherein the unit characters of one of the partners will supply the deficiencies of the other. Such an arrangement would without doubt produce an improved human animal as it improves the lower animals, but the eugenists do not expect to place human mating upon such a plane. Their object is to check the breeding of human defectives, and thereby increase the ratio of normal people.

The necessity for such action has already been pointed out. It has been shown that the defectives are rapidly increasing in this country, and it has been estimated that they already cost the country 100 millions of dollars annually. Aside from this enormous expenditure of money that would go far toward the uplift of humanity, if it could be utilized for that purpose, there is the long black trail of mental darkness, ill health, poverty, and crime that follows the blight of mental defectiveness. A large proportion of criminals, paupers, prostitutes, drunkards, and ne'er do wells are mentally defective. The Chicago Vice Commission states that eighty per cent. of all women between twenty and twenty-five years of age, from houses of ill fame, who were examined, exhibited a mental capacity of children from twelve to fifteen years of age. It has been found that at least twenty-five per cent. of criminals are feebleminded. Of 100 children committed to the Detention Home in New York by the Juvenile Court, sixty-seven per cent. were found to be feebleminded. Such facts as these have caused thoughtful people to pause and consider where such conditions will lead if they remain unchecked.

Of the measures proposed to meet these conditions the following are chiefly advocated: 1. Segregation; 2. sterilization; 3. control of marriage; and, 4. general education of the public as to existing conditions, and the measures proposed to meet them.

Segregation.—In many respects the segregation of defectives into colonies where they can receive care and attention, and be given such education and training as they can take, is a measure that appeals more strongly to the animal instincts, because it provides for the happiness and well being of these unfortunates under the best obtainable conditions. Goddard, however, in his pamphlet Sterilization and Segregation, points out some of the difficulties in making segregation effective. The first of these is the enormous cost of properly caring for the existing defectives, and their increasing numbers. He states that the Royal Commission of England, after an investigation that lasted four years, found that the feebleminded were increasing at twice the rate of the general public. He points out that there are at least 1,500 feebleminded children in New York city alone, by which it is presumed he means children whose feeblemindedness is evident, and does not include children whose defects are not sufficiently apparent to warrant their assignment to this class. If New York city has this number of feebleminded children—and it is probable that the numbers are under rather than over estimated—it may be safely assumed that the ratio is equally great in other sections of the country. The burden of cost for the care of defectives has grown so great that its limits are rapidly approaching, and the time is not far off when some radical measures must be taken to reduce these expenditures.

Another obstacle in making segregation effective is the difficulty of getting feebleminded children into colonies. Unless a child is an idiot, it is frequently difficult to convince the parents that it is defective, and even when that is done, it is not always easy to obtain their consent to take the child to an institution. There are also many high grade defectives whose defects do not show until they have reached adult age, and parents object to placing such children in an institution. It is impossible to have laws passed requiring that such persons shall be sent to an institution, and even if such laws were passed they could not be made effective. The indignation that would follow an attempt to send a high grade defective child to an institution, in opposition to the wishes of its parents, would probably produce riots. It is doubtful if such a law would be constitutional, and if it were, it is questionable whether it would not do more harm than good. There is also the difficulty of determining
what constitutes defectiveness to a sufficient degree to make commitment to an institution necessary. Until a standard of normality can be adopted it would be difficult to draw the line on high-grade defectives, and this would require a board of experts, which would not always be available, and whose findings would not always be accepted. It is evident, therefore, that there seems to be no prospect for the adoption of such laws within the near future, and without some measures whereby the greater proportion of defectives can be placed in institutions, segregation alone can not be made effective.

Even with those who are placed in institutions it is not possible in the present state of the law in many States, to prevent such persons from being legally married, and having children, or having children without being married, which it is impossible to prevent in all cases unless these persons are absolutely segregated and never allowed any liberty, a condition that it is not possible to enforce in all cases. In view of these facts it seems evident that segregation alone cannot be relied on, to furnish the necessary relief for existing conditions. The benefit of institutional training to defectives is great; many have been greatly helped, and their lives made happier by it, but its capabilities as a broad economic measure for decreasing the number of defectives are limited.

Sterilization.—Those who have given the closest study to the subject are the strongest advocates of sterilization for defectives. It offers the most effective method for stopping procreation without otherwise interfering with the sexual functions, nor does it injure the health. It consists of vasectomy in the male, and removal of the ovaries, or section of the Fallopian tubes, in the female. The operation in the male is exceedingly simple. With the female the operation is less simple, as it involves opening the abdominal cavity and removing the ovaries, or ligating and severing the Fallopian tubes. However, abdominal section under modern aseptic methods is an operation attended with but little danger, and is being daily performed. There seem to be no ill effects to the patient from the operation; on the contrary, the operation is often followed by marked physical and mental improvement.

Dr. Charles V. Carrington, lately surgeon to the Virginia Penitentiary, states, in his paper, Hereditary Criminals, that he has performed the operation upon several inmates of that institution, with marked benefit in each case.

It is generally conceded by students of the subject that sterilization of the markedly feebleminded, the chronic insane, and habitual criminals is not only a most desirable measure but one that is necessary.

Eight States have passed laws to this effect, but in none of them are they being executed at present. Only one State has applied the law, and there the operation has been abandoned at the suggestion of the Governor on the ground that the law, as it stands is probably unconstitutional. Goddard says: "The strong argument against the constitutionality of the law is that it is 'cruel and unusual punishment.' The idea of punishment comes into the question because criminals are included in it." He thinks if the term "criminal" were left out of the law, which should be made to apply only to the feebleminded (which in many cases would include habitual criminals), the idea of punishment would disappear. He believes that segregation in conjunction with sterilization will give the best results. It is believed that opposition to sterilization will decrease as the idea grows more familiar. At present there is some stigma attached to it, but if the operation is adopted as a measure for the benefit of the individual, and it becomes a common practice for the improvement of the mental and physical condition of the patient, much of the prejudice against it will disappear.

The patients themselves do not as a rule desire to have children, and if they are convinced that their sexual functions will not be otherwise interfered with, and that they will be improved mentally and physically, it is believed that many of them, at least, will readily consent to the operation.

Dr. Carrington says that he has been requested by patients to perform the operation on them. If physicians will appreciate the benefits to feebleminded patients, as well as to society at large, following the operation for sterilization, much good can be accomplished. It has been suggested that freedom from the possibilities of having children would lead to increased immorality of those who have been sterilized. Goddard says that it is the opinion of the social workers and others who come in contact most largely with this class of people, that the fear of having children does not act as a deterrent to immorality to any appreciable extent, and it is believed that the possibilities for increased immorality are far outweighed by the advantages to be gained in preventing the further production of degenerates.

Regulation of Marriage.—One of the most promising measures for limiting the reproduction of defectives is the regulation of marriage. In many States there is present no bar to the legal marriage of paupers, diseased, or defective persons. Consequently we have inmates in almshouses, who are being supported by the State, marrying and producing children, many of whom are defective, to add to the already heavy burden of the State.

Dr. H. W. Dew, in a paper read before the South Piedmont Medical Society, Lynchburg, Virginia, November, 1912, states that in one almshouse fifteen feebleminded women had given birth to illegitimate children, within a period of six weeks. This is not only an injustice to the State but also to these children, who are brought into the world under the most unfavorable conditions, both of heredity and environment, and whose chances of becoming useful citizens are most remote. It is difficult to understand the process of reasoning, if reasoning it is, that will permit paupers and defectives, who do not support themselves, to reproduce their kind to be also supported by the State. It is establishing an endless chain of degenerates, that multiply in ever increasing numbers with the passing years.

We have laws to prevent damage to property and to individuals, and there is every reason why these laws should be extended to protect individuals in the aggregate, viz., the State. One of the
most urgent reasons for the enactment of laws regu-

lating marriage, in addition to restraining the in-
crease of the feebleminded, is to prevent the mar-
rriage of persons suffering from transmissible dis-
ease. It is estimated that seventy-five per cent of the
all special surgical operations on women are made
necessary by reason of gonococcal infection. It is
stated that from sixty to seventy-five per cent of
all adult males have been infected with gon-
orrea at some time. It is estimated that twenty-five
per cent of congenital blindness is caused by go-
ococcus infection received at birth. Ten per cent of
the population of the United States is said to be
syphilitic. Syphilis is a disease that is transmit-
ted from parents to offspring in full virulence,
often killing the child outright, or blighting normal
development.

Dr. Prince A. Morrow estimated that when the
father alone is infected with syphilis the mortality
among children is about thirty-eight per cent.
When both parents are infected the mortality av-
erages from sixty per cent. to eighty per cent. Fully
thirty-three per cent. or one third of all infected
dead die within the first six months. Those
who do not die within this period, continue to live
as mental or physical defectives. It is stated
upon what seems to be good authority that one out
of every four cases of hereditary insanity is due to
syphilis. Thirty-eight per cent. of children with
tuberculous hip disease are said to be congenital
syphilitics; in tuberculous meningitis the proportion
is said to be sixty per cent., or more than half.

Syphilitic children have “poor constitutions,”
that is, they have but little resisting power to dis-
ease, and die when a normal child would recover
under like conditions. Dr. H. E. Jordan, in his pa-
per, The Eugenical Aspect of Venereal Disease,
quoted Dr. Morrow, says: “The chances of a
syphilitic child dying under the age of fifteen are
said to be seven times as great as those of a child
free from syphilis. As evidence of how hereditary
syphilis lessens resistance, a careful analysis of all
infectious diseases in children shows that, exclusive
of widespread epidemics, the chances of a syphilitic
getting typhoid fever are two and one half times
as great as for a nonsyphilitic; for scarlet fever,
three times; for measles, three and one half times;
and for diphtheria, seven times.” An equally care-
ful analysis for other diseases would probably show
that hereditary syphilitics are also more susceptible
to them. Syphilis blights all that it touches, and
leaves in its train enfeebled and deformed bodies,
darkened and perverted minds.

It not infrequently occurs that a pure and inno-
cent girl is infected by her husband with gonorrhea
or syphilis. Within a few years she becomes a
physical wreck, and thereafter drags out a miser-
able existence of pain and suffering, finally dying
an untimely death, a victim of the system that per-
mits the mating of the diseased and unfit. Aside
from the sentimental aspects of such cases, how-
ever deeply that may appeal to us, the economic
loss to the State by this destruction of some of its
reproductive agents is serious. But for this blight
such women could have contributed to the welfare
of the State and nation, by bearing strong and
healthy children, without which no nation can long
survive.

To meet these conditions efforts have been made
in several States to have laws adopted prohibiting
the marriage of the diseased, feebleminded, or
otherwise unfit. The laws proposed vary somewhat
in detail, but contain the essential provision
that no marriage license shall be issued until a
medical certificate is presented, showing that the
persons applying for a license to marry are not fee-
bleminded, insane, or suffering from certain trans-
mittable diseases, and providing punishment for
violation of the law. Rules for the conduct of these
examinations are to be prepared by the State
boards of health, which shall have supervision of
them. Provision is also made for the punishment
of physicians who issue false certificates.

It seems desirable that these laws should be ex-
tended in their scope to include a declaration that
all marriages contracted in violation of the law
should be null and void, as otherwise there might
be some question on the subject. It also seems de-
sirable that some provision should be made to de-
termine the qualifications of physicians who may
issue such certificates, and provide for the free ex-
amination of persons desiring to marry.

In order that laws regulating marriage may be
effective it is necessary that some thoroughly prac-
tical plan be adopted, otherwise the laws will not
be enforced, and the objects sought to be attained
will be retarded rather than advanced. Just what
this plan should be will require careful considera-
tion and that every aspect of the subject be scruti-
nized, but it seems that the plan must involve co-
operation between the State boards of health and
the physicians throughout the States. There are
but few practising physicians equipped with the
necessary facilities or experience to make the ex-
amination to determine if a given individual is suf-
fering from latent syphilis or gonorrhea. The ex-
amination of the blood and discharges would have
to be made in a laboratory. It is possible that a
plan might be evolved whereby a report of each
physical examination, made by physicians, should
be forwarded to the State board of health, which
would issue the necessary certificate, based upon
the report of the physician, and supplemented by
such laboratory examinations as the board might
consider necessary. For the present, at least, it
seems wiser that any law for the regulation of mar-
rriage should restrict the medical certificate to a
statement that the candidate for matrimony is not
feebleminded, insane, or an habitual criminal, and
is not suffering from active tuberculosis, syphilis, or
gonorrhea.

If some such plan can be put into execution it
is believed that it would be a step in the right di-
rection, and changes could be made from time to
time, when experience had demonstrated their ne-
cessity. It can not be hoped that such a plan would
be perfect, or that it would reach all cases, but it
would be directed to the greatest good to the great-
est number. The question has been taken up by
various local churches in different parts of the
country, and the ministers of those churches refuse
to perform the marriage ceremony unless a medical
concerning the etiology of hypertrophic pulmonary osteoarthropathy. With a Report of Five Additional Cases.*

By Harlow Brooks, M. D.,
New York,
Professor of Clinical Medicine, University and Bellevue Hospital Medical College.

The general characteristics of this disease picture are now quite commonly known, so that failure to recognize it can no longer be held accountable for the relatively few cases reported in the literature of medicine. Neither can the small number of instances recorded be solely explained from the excessive rarity of the condition, for sporadic cases, particularly of the minor types, occur not uncommonly in almost every clinic. For example, in many cases of chronic empyema lesions of this character appear in mild but unmistakable form, to disappear when the pleural abscess is evacuated. The infrequency with which the condition is reported must, then, be accounted for by the fact that clinicians take very little interest in the process, since it is universally believed to be secondary in nature and to represent but a relatively unimportant phase of a general process.

Although I am myself also of this opinion, my interest has been kindled in the etiology of the syndrome, not only in an attempt to explain its origin, but also because I have long wondered why it was not present in conditions in which it would be naturally expected to develop. This case analysis and study is designed to clear up these phases of the subject. The chief interest must now centre in an explanation of why the characteristic deformities appear. From a cursory review of the literature of the subject the point of greatest perplexity would seem to be the widely different conditions in which it occurs, and the reason why it does not develop more frequently in apparently analogous circumstances, if, as Marie originally postulated, the picture is entirely secondary in nature.

The most consistent and essential anatomical alteration appears to be the osteopoikilosis osificans affecting chiefly those parts of the long bones which are distally located: rather than, than of, the articulations. In young persons particularly, however,
ever, the bones entering directly into the articulations appear to be chiefly involved, apparently more because it is in these locations that hyperplastic processes, as it were, are more naturally or easily incited than from any inherent peculiarity of the articulations themselves. Hence it would seem that the condition is unfortunately termed an arthropathy, for it appears to be chiefly the peripheral nature of the bones, rather than anything else, which determines the process at these points.

As to the precise histological type of the bony changes, considerable natural variation exists, as is also the case in most other forms of hyperplastic and retrogressive bony processes. As for the changes in the soft parts, little discrepancy exists when the anatomical facts are simmered down to their essentials, and are divested of the natural variations which occur in practically all pathological manifestations. The clubbing of the digits is thus shown to be chiefly due to changes in the soft tissues, perhaps mostly in the areolar connective tissue. Whether fat production is the chief change, as stated by Thoborn, or the connective tissue elements of the true skin, as asserted by Hirschfeld, is relatively unimportant. Sternberg found round cell infiltration and thickened blood-vessels, in the pads which occur almost constantly in the clubbed fingers. Is it not, however, to be expected that such alterations and variations should develop in digits in which the capillary circulation is always found to be so markedly slowed and changed? Although it is admitted that the enlargement of the ends of the fingers and toes is chiefly due to changes in the soft parts, X-ray and post mortem studies demonstrate that occasionally an osteophytic formation is found associated with the alterations in the areolar tissues. The lack of association with other trophic alterations, and the almost absolute disassociation of this syndrome from all neuropathic diseases, indicates the absolute separation of the condition from the neuropathic arthropathies, and thus far microscopic studies of the diseased tissues also exclude lesions of this character.

The more recent histological studies of the disease, especially the careful work of Franchini (Revista critica di clinica media, xi, p. 745, 1910), corroborate the constancy of the above outlined lesions. The studies of Ball and Alamar-tine (Revue de chirurgie, Paris, 1908, xxxviii, p. 472; Gazette des hôpitaux, Paris, lxxxv, 1912, p. 1587) and Lienaux (Bulletin de l'Academie royale de medecine de Belgique, Bruxelles, 4 s. xxiii, 1909, p. 108) on the lower animals in apparently similar disease pictures completely identify the changes occurring in these animals as similar to those in man, at least in their essential substance. It is, then, to the study of the etiological relationship of the primary disease changes to the characteristic deformities that I particularly desire to draw attention, and for this purpose I have attempted to carefully analyze the cases reported since 1903, at which time Janeway (American Journal of the Medical Sciences, NS. cxxvi, 1903, p. 563) brought the subject up to date in so far as case analysis is concerned.

I have chosen to limit my analysis to the instances thus recently reported because there is no doubt both that pulmonary osteoarthropathy is itself better understood now, and particularly that acromegalia and the numerous arthropathies are now more certainly differentiated. To this list I wish to add the case reports of five new instances of this condition; which brings the total number of cases which I have personally studied and reported up to nine.

Notwithstanding the fact that the profession is now generally correctly informed in regard to pulmonary osteoarthropathy, one still finds in the literature a certain number of cases reported which cannot be considered as true pulmonary osteoarthropathy. Such is the instance recorded by Mercy and Guile-mot (Bulletin et memoires de la Societe medicale des hopitaux de Paris, 38. xx, 1903, p. 328), in which the description of lesions and symptoms seems to indicate that the case was one of rheumatic arthritis complicating rachitis. Case five of Symes-Thompson (Medico-Chirurgical Transactions, London, lxxxvii, 1924, p. 83) is also in the doubtful class because of the fact that the description of the lesions, taken together with the history
of congenital syphilis, suggests strongly the possibility of a luetic arthritis, by no means a rare condition, although aside from undiscovered possibilities, since the etiologic factor was lues, no pulmonary or cardiac explanation of the bony changes is given. None the less, in recognition of the acknowledged familiarity and learning of the author in regard to this disease, this case can certainly not be excluded, and must be considered in our analysis. Symons (Indian Medical Gazette, xxxix, 1904, p. 16) records also a doubtful case which, if one relied solely on the author's description, would apparently more completely fit into the picture of an arthritis deformans, perhaps, or that of an incompletely developed acromegalia; but, as with the instance just mentioned, this one also cannot be definitely excluded. Somewhat similar to this case is that of Koll (Deutsche medizinische Wochenschrift, xxxii, 1906, p. 527), in which the marked changes noted in the lower jaw and in the tongue, suggest acromegalia, particularly as no etiologic factor is presented except the history of a long standing intestinal toxemia. The history and course would further suggest the likelihood of an acromegalia. Shaw and Cooper (Transactions of the Clinical Society of London, xl, 1907, p. 259) describe under this heading a case which is definitely one of simple clubbed extremities due to heart disease of congenital origin—there is no ground whatsoever in so far as the meagre report of this case goes why it should be included for a moment as one of pulmonary osteoarthropathy. Chrysospäthes (Zeitschrift für orthopädische Chirurgie, Stuttgart, xx, 1908, p. 406) records a case in which multiple arthritis, partly of a supplicative character, was present. Although the urine showed a diminished excretion of phosphorus, the radiographic examination showed osteoporosis and thickening, and we cannot but agree with the author that the case was not one of pulmonary osteoarthropathy. Because of the present inaccessibility of the journals in which the reports were printed, in the appended bibliography is included a list of eight articles which could not be reviewed in time for the meeting of this society.

With these possible exceptions, considered as among the questionable cases, all of the other instances reported are apparently true examples of this condition. Of the total of fifty-seven cases thus collected it is very significant that forty-four instances showed definite pulmonary or pleural lesions which were supposed to be of sole or chief etiologic import. To this list should also be added the instance recorded by Thiraloix and Jacob (Bulletin et mémoires de la Société médicale des hôpitaux de Paris, 3 s. xxxix, 1910, p. 51), which is undoubtedly a typical instance of the disease, and in which the history states that the patient was a chronic sufferer from asthma. At six years of age he had a fracture of the thorax, he had bronchial catarrh and emphysema, and yet the authors record the pulmonary condition as "normal," and further state that the etiologic factor was not apparent. For obvious reasons I include this case with my list of those showing lesions of the pleuropulmonary tract; thus bringing the total list of cases of this type up to forty-five. It is also quite probable that case five of my newly recorded instances is one of pulmonary origin, but inasmuch as the history is not clear on this point, and as we were unable to definitely locate either pulmonary or other primary lesions, this case is held in the doubtful list as regards etiology.

As to the precise character of the pulmonary lesions, twenty-eight cases showed either pulmonary fibrosis, chronic bronchitis, or bronchiectasis; six cases showed neoplasm of the lungs; one, atelectasis of long standing; four, empyema; and six, pulmonary tuberculosis. It should be noted that in all these instances deficiencies in the pulmonary parenchyma with presumably deficient pulmonary oxidation and extensive capillary compression were manifest. Seven cases are recorded in which mediastinal neoplasm appeared as the most likely etiologic factor. In every instance of this group either clinical signs or autopsy findings showed invasion of the pulmonary tissue, as well as that of the mediastinum. Two of these instances were cancer, with apparently secondary invasion of the mediastinum and lung. Two instances were sarcoma; one, endothelioma; and two, growths of unknown nature. One of these, case three of Symes-Thompson (Medico-Chirurgical Transactions, London, lxxxvii, 1904, p. 85), had been previously reported as free from pulmonary lesions, but later study developed the finding here recorded. Two cases remain in which no apparent etiologic factor is present, the case of Wolfsohn (Berliner klinische Wochenschrift, xlvii, 1911, p. 1031), in which lues was most likely the etiologic factor, and case five of my own newly recorded group. The remaining five cases are those of Mercy and Guillemot, discussed and excluded above, in which the probable etiologic factors are stated to be rachitis and rheumatism, case five of Symes-Thompson, the very questionable case of Symons, that of Koll, and one of my own. It would thus appear that of the total number of fifty-seven cases, all except five showed invasion of the lung tissue either primarily or secondarily. Of these five cases, two only are certainly examples of pulmonary osteoarthropathy and the remaining three, while included in the group, are doubtful instances.

From this group it then appears that those of mediastinal neoplasm may, to all intents and purposes, be included with those in which the process appears primarily in the lung parenchyma or pleura. Inasmuch as the effects on the peripheral circulation and on the blood are substantially the same in mediastinal neoplasms with pulmonary involvement as in primary obliterator pulmonary disease, it would seem just that these two factors be considered as essentially identical.

Basing, then, our consideration of the etiology on the prevailing factors present in the recently reported cases, it would seem that the end results in practically all undisputed instances are peripheral venous stasis, due to mediastinal or pulmonary compression with limitation of pulmonary action and capillary circulation.

Circulatory lesions exclusive of mediastinal neoplasms were reported as present in but seven of the cases analyzed, and of these, four instances were such relatively unimportant (etiologic) al-
terations, found at post mortem as brown atrophy of the heart (two instances) and fatty heart (two instances, one with a coronary sclerosis). In one case a clinical diagnosis of "possible myocarditis" was made, and in but a single instance was the circulatory lesion judged by the reporter to be etiological. This was the certainly incorrectly diagnosed case of Shaw and Cooper (Transactions of the Clinical Society of London, xi, 1907, p. 250), in which a congenital defect in the intraventricular septum was found. Inasmuch as this case differed in no respect from the usual case of clubbed extremities universally seen in congenital heart defects, it cannot be classed as one of hypertrophic pulmonary osteoarthropathy and may therefore be safely discarded, as before mentioned.

Since the anatomical characteristics of this symptom complex are essentially those of proliferation of the periosteum at the distal ends of the long bones, not truly an arthropathy, and proliferation of the soft tissues in the peripheral portions of the body associated with local congestive conditions, it becomes important, in an attempt to explain the etiology of those lesions, to consider the age at which these changes usually develop. In forty-three instances, the probable age of onset could be determined with a fair degree of accuracy. It was found that the average age of onset was at 17.55 years. A review of the statistics collected in Jane-way's article, as in that of others who have also compiled the literature in regard to this condition, showed the notable fact that the neoplastic instances as a rule occur in those of a more mature age. In this series this same feature is also apparent, and it is found that the average age at onset in cases of probable neoplastic origin is 40.5 years.

That a hyperplastic process should spring up in the tissues of the body in adult life in cases of new growth is, of course, quite in consonance with our present conception of the relationship of new growth formation to tissue hyperplasia. The similar tendency toward general tissue hyperplasia in tuberculosis is also well established, and it need therefore cause no surprise when it occurs at any age. The average age of onset in cases due to tuberculous disease of the lungs is 20.6 years. When cases of neoplastic and tuberculous origin are excluded from our analysis it is found that the average age of onset of pulmonary osteoarthropathy is but 12.67+ years, which would then place the disease as definitely of juvenile origin, except in tuberculous and neoplastic instances. That in youth hyperplasia should be easily excited in the periosteum of the distal portions of the long bones and in the peripheral soft tissues of the body, where chronic passive congestion of these parts is associated with deficient oxygenation and capillary stasis, is, then, but a condition or result to be entirely expected.

It is a well-established fact in pathological anatomy that cyanosis, especially that due to pulmonary lesions or to mediastinal compressions, causes the most marked stagnation in the periphery of the circulatory tree, namely in the fingers, toes, and face. Recognizing the universality of clubbed fingers and toes in this symptomatic complex, it should then be expected that like changes should appear in the face, just as they so appear in most analogous conditions. It would therefore seem that the signs of globular nose tip and malar puffiness should be present in this disease. Such was the case in the four instances originally reported by me (New York Medical Journal, December 16, 1911), and in four of the new instances reported in this paper. In so far as one may depend upon illustrations and text descriptions, these signs were present in several other instances recorded in this analysis. In case three of the Symes-Thompson group the patient noticed that the nose was notably large at the tip. The questionable case of Symons shows this feature, but this is probably not an instance of true pulmonary osteoarthropathy. The plates exhibited with the cases reported by Wynn (Birmingham Medical Review, lv, 1904, p. 212) show an apparent malar prominence and globular nose tip. The author, however, reports the face as normal, and one must recall in the study of all photographs, especially those not skillfully posed, that there is a tendency toward the production of an apparent larger nose tip through foreshortening. The photograph of the case of Cagnetto (Rivista veneta di scienze mediche, Venezia, xlv, 1906, p. 15) shows an apparent prognathism and prominent globular nose tip. The questionable case of Koll, already mentioned as probably one of acromegalia, shows this change quite typically. Kruger (Virchow's Archive, clxxx, 1906, p. 43) mentions changes in the bones of the skull of a character probably similar to the changes to which I call attention. In the article of Ball and Alamartine (Revue de chirurgie de Paris, xxxviii, 1908, p. 472) these observers show, from their studies of a similar disease in the dog, that any part of the skeleton, including the bones of the face, may be involved. The case report of Mouisset and Orsat (Lyon médical, cxvii, 1911, p. 337), presents a plate in which a large globular nose is apparently present. Wolfsohn (Berliner klinische Wochenschrift, lviii, 1911, p. 103) reports that the nose became broader and plumper, and that the inferior maxilla became more prominent; features which the plate published with the papers shows in an apparently definite way. Thus, of the fifty-seven cases included in this analysis, fifteen probably show in greater or lesser degree this entirely to be expected facial alteration, which has apparently escaped the observation of most students of the disease thus far. In reviewing, for my own satisfaction, the literature of this disorder published before the period at which I chose to begin the present analysis, I find also not infrequent plates indicating this peculiarity.

Of direct bearing on the question of the etiology of pulmonary osteoarthropathy is the fact that the instances in which improvement followed treatment were all those in which pulmonary lesions were apparently the etiological factor. When these lesions were of such a character as to permit of successful treatment or amelioration, improvement in the bone and soft tissue deformities are reported. Acting on this suggestion in a case of my own (Case IV, New York Medical Journal, December 16, 1911) vigorous and persistent treatment designed to relieve the pulmonary lesions was continued over two
years' time. In addition to affording great relief from the conditions of fetid bronchitis and bronchiectasis, complete disappearance of the bone pains has followed, together with a considerable decrease in the size of the fingers, toes, and distal portions of the arm and leg bones. Similar results are recorded by Sevestre, Symes-Thompson, Wynn, Puyhaubert, Alexander, Robinovich and Barot, and Pie. Since all these instances were those of supposed pulmonary etiology, and since the improvement of the bony and soft tissue deformities appeared coincident with the betterment of the thoracic (pulmonary and pleural) disease, it would seem beyond doubt that a causal relationship existed between the primary and the secondary lesions.

It is unnecessary in this place to go fully into the discussion of all the various theories, advanced to explain the almost invariable association of pulmonary, pleural, or mediastinal lesions in their relationship to the development of the characteristic osseous and soft tissue changes of pulmonary osteoarthropathy. The original theory of Marie must, however, be mentioned, since it was the first to be founded on a study of the pathological anatomy of the condition, and also the first which recognized the dependence of these lesions on mediastinal, lung, or pleural changes. Marie believed that the deformities were due to the absorption of some toxic substance from the lungs and pleura, which were the seat of an inflammatory process. This theory received a certain amount of corroboration from those numerous instances of empyema and bronchiectasis in which the absorption of a septic poison was quite justly assumed to take place. That the absorption of septic materials alone is insufficient to cause the deformities is clear from their absence in such conditions as hepatic abscess, chronic sepsis, osteomyelitis, and so on. This theory has, it is true, received support from some reported cases; none such, however, appear in the recent literature—since the differential recognition of the various arthritic processes has become sufficiently certain. This theory has been discredited also by frequent examples of pulmonary osteoarthropathy in pulmonary fibrosis or atelectasis, where neither bronchitis or bronchiectasis, or other septic absorption can be assumed to take place, and also by the frequent cases of mediastinal tumor which are also devoid of this possibility. It is obvious, then, that some other explanation must be advanced to clarify this association of lesions, especially because analysis of the most recently, and probably most accurately, observed cases indicates the practically invariable association of mediastinal, pulmonary, or pleural processes in the disease.

Apparently the true key to the association of this syndrome with mediastinal and pulmonary defects is furnished in Zeigler's discussion of the dependence of passive hyperemia on pulmonary defects. Briefly, he states that in consequence of disease of the lungs, and also of the pleura in that it displaces the lung, the respiratory movements of the chest are hindered, and thereby a withdrawal of an efficient aid to the circulation occurs. In addition, and of even more definite influence, are those diseases which, as in pulmonary fibrosis or pulmonary compression from empyema, cause an impermeability of a more or less great area of lung capillaries. Exactly similar conditions are produced, as Zeigler pointed out in his memorable lectures on hyperemia, by aneurysm of the aorta or by tumors situated at or about the root of the lung, and which thereby compressed the pulmonary arteries. A hyperemia so produced naturally is most marked or longest present in the peripheral portions of the body where, owing to simple mechanical reasons, it becomes most manifest in the hands and wrists, the feet and ankles, and, to a lesser degree, in the face. The effects of such standing passive hyperemia on bone or on areolar connective tissues is to induce hyperplasia of those parts of the bone or soft tissues which are most susceptible to hyperplasia, that is in the periosteum and the areolar connective tissue. Hyperplasia in these structures is the natural outgrowth of a passive hyperemia. This result is manifestly more likely to be carried on to a marked degree in young tissues, those which are physiologically most inclined to hyperplastic growth. Hence it is that the changes are the more pronounced in youth, and less so or absent in adult or old age. This would apparently account for the almost strict limitation of pronounced cases of the deformities characteristic of pulmonary osteoarthropathy to those instances in which the process originated during youth. It also accounts for the failure of these changes to develop to such a degree, or so frequently, when the pulmonary obstruction occurs after youth. When the impediments to pulmonary circulation and respiratory movements are removed as after treatment the deformities should be checked or retrogress, as instances in the recent literature have shown them to do in pulmonary osteoarthropathy.

The reason why the mediastinal growths produce changes precisely similar to those of direct pulmonary impairment is apparent and needs no further explanation.

That defective oxygenation of the blood may also play a rôle in this tissue hyperplasia is possible, since it is well known that suboxyg enated blood or a passive congestion invites abnormal tissue hyperplasia, as witness, for example, the interstitial hyperplasia in chronic congestive diseases of the liver and spleen. Septic absorption may perhaps play a similar rôle in some instances, but that it is in any way an essential in the evolution of these deformities would appear to be negative by the evidence adduced from the analysis of these recently reported cases of pulmonary osteoarthropathy.

In conclusion, then, it would seem that a quite sufficient explanation of the lesions of pulmonary osteoarthropathy, and their dependence on pulmonary functional limitation or on such mediastinal growths as impede pulmonary circulation, is furnished by the resultant passive hyperemia which these conditions produce in the distal portions of the body. The lesions are most marked and most likely to appear in those instances where the process begins in early youth because all tissue hyperplasia is most easily excited during this period. They appear in lesser degree, or not at all, when, as in most cases of pulmonary tuberculosis, the pulmonary and circulatory impediment develops at a period of life when hyperplasia of the periosteum and areolar connective tissue is less readily excited.
BROOKS: hypertrophic pulmonary osteoarthropathy.

CASE REPORTS.

Case I.—Montefiore Home, J. P., male, aged nineteen years. Born in Russia; single, occupation, tailor. History: Father and mother alive and in good health. One brother and one sister alive and well. Two sisters and one brother died in childhood. No history of tuberculosis, syphilis, or of chronic metabolic or nervous disease.

Previous History: Patient was the fifth child, healthy from infancy up to about the age of ten. Habits: Appetite always good, bowels regular, used to sleep well. Drank tea and coffee moderately. In the use of beer and wine, he never showed any inclination. Denied all sexual relations, venereal diseases, or masturbation. Worked as a tailor in dust laden air and under very poor hygienic surroundings. Said that in shop where he was employed a tuberculous patient was working.

Present Illness: As a child he had measles and whooping cough; at the age of nine he had pneumonia on left side; at the age of twelve, and again at fourteen, had other attacks on the same side.

Sideral History: Died back about five years. At that time, while recovering from pneumonia, he began to cough and expectorate moderately. These symptoms became aggravated at times and continued until about two years ago, when he began also to feel quite weak. About three years ago he complained of burning sensation in the back; also noted slight bulging of back on the left side. This gradually increased, so that a deformity resulted which made him walk about in a stoopshoudered manner. He had a left sided inguinal hernia of about four years standing. He has become much emaciated. Chemistry shows.

About a year and a half ago noted that his sputum was blood streaked. This persisted for about one week, then ceased, but again reappeared in June, 1912. The sputum has been in color, for the last three months, and has a sweetish, nauseating taste. At examination he chiefly complained of burning pain in back and legs, so severe that he could not walk; felt very weak generally. During his coughing attacks he felt dizzy and had a sensation of heat. His symptoms became referable to the constent coughing. Slept well at night, but was obliged to get up to urinate about twice every night; passed large quantities of urine each time. During the day he urinated about every half hour. On two occasions the abdomen became distended Considerably. For the last three months he had become very dyspeptic on slight exertion. He was very tired and weak, and complained of palpitation. One month ago edema appeared in both lower extremities below knees, and developed to such an extent that he was confined to bed for three to four weeks after external applications. There were no symptoms relating to the alimentary tract. Chief complaints: (1) Bulging of entire left chest; (2) marked cough and copious, fetid, sweetish tasting sputum, occasionally bloody sputum; (3) complaints of burning sensations, slight exertion; (5) asthma; (6) pain and tenderness, in worms and ankles.

Physical Examination: Young adult, of medium stature, poorly nourished. Muscularly flabby; skin, cool, dry, and pale. The expression is that of anxiety and suffering. Head, normal shape, no scars, depressions, or elevations; except that malar bones are very prominent and the end of nose is globular. Eyes show normal pupils; no ocular palesies or nystagmus. There is very marked clubbing of fingers and toes, and the distal extremities of long bones of ankles and legs are enlarged and tender. X ray examination shows the clubbed fingers and toes to be chiefly due to hyperplasia of the connective tissue, but the distal extremities of the fingers are of an acro-osteitis. Marked bulging of entire left chest; seemingly this half of thorax is displaced to the right, and there is marked sclerosis in the dorsal region, the convexity directed towards left. There is very marked loss of height of lower rib. In the upper half of left axilla a tympanic note is given. Posteriorly on the left side there is a tympanic note about the level of the spine of scapula, and above it to the fifth dorsal vertebra; diminished resonance to dullness from fifth dorsal vertebra down to base. Respiratory murmurs exaggerated over entire right lung; expiration is about 3 inches in duration to inspiration. Respiratory movement is diminished all over left lung, and markedly so below level of fourth rib anteriorly, in the axilla (left) and posteriorly from level of fifth; no rales heard. Heart: Apex beat located in fifth space, nipple line. Cardiac dulness above left lower border; diaphragm at level of fourth rib. The lower three quarters of an inch beyond nipple line and on the right to the midsternal line only First sound is of fair muscular quality, best heard in fifth space in nipple line; no murmurs or abnormal sounds detected. Vertebral bowing signs of thickening; radials are equal, showing moderate tension; are compressible, regular; rate 100 a minute. Abdomen: Soft; flat; no areas of tenderness nor rigidity; no palpable masses; pampinum adiposus scant. Bowel sounds normal; stool; not evacuated. Rectal examination shows about two inches below costal margin; the inferior border of liver is smooth and firm. Spleen and kidneys are not palpable. The neurological examination gave negative findings.

Urine Examination.

Albunin, 10 per cent. (volume). Sugar, none. Specific gravity, 1.015.

Marry finely and coarsely granular, uric acid, absence. casts. Acid and diacetic acid, absent. Sediment.

Sputum purulent, contains much pus; occasional epithelial cells; no elastic fibrils; blood cells present; bacteria very abundant, mostly pyogenic organisms; no tubercles found. Chemical tests show much albumin present.

Diagnosis: Chronic bronchitis with bronchiectasis, pul- monary fibrosis and chronic adhesive pleurisy, chronic parenchymatous nephritis, and possibly spinal caries, hypertrophic pulmonary osteoarthropathy.

Course: The patient was confined to bed because shortly after entering the hospital marked edema, ascites, and defective fluid excretion developed. Under hot packs, reduced fluid intake, saline purgation, and salt free diet, the patient showed much relief. After a time, the sputum became much reduced in quantity. The odor diminished, and the patient's general status was much improved. Especially notable was a decrease in the tenderness and pain in the wrists and ankles and an apparent decrease in the clubbing of fingers and toes. He was still confined to bed, and would probably remain there for a considerable time. Physical and X ray examination of the chest showed no apparent morphological changes, but the general picture was much improved.

Case II.—Montefiore Home, Application No. 14142, Mrs. T. W., aged thirty, occupation, cook; born in Russia; in United States eight years.

Family History: Father died at the age of eighty; mother alive and healthy. Had two children, one of whom died from consumption. No rheumatic, malignant, or syphilitic history.

Personal History: First child, naturally born, and breast fed. Had smallpox at the age of eight; malaria at age of ten. First menstruated at seventeen; regular twenty-eight day type, five days' duration. Married at the age of eighteen; husband twenty-eight. Had had two children, both of whom died in infancy from intestinal disturbances.

Habits: Tea in moderation; no alcohol. Lived under good sanitary conditions.

Present Illness: Was comparatively healthy until five years ago, when she was taken sick with pneumonia; had chill, pain in chest, hemoptysis, and high fever. Was very ill for six or seven days, when she improved somewhat, but the cough persisted, and expectoration became very abundant and was associated with slight daily rise in temperature. About two months before entering the hospital, patient had a severe pulmonary hemorrhage which left her in a very weakened condition. After this the cough became less severe and she improved slowly, but was obliged to remain in bed for one year and a half after this attack. The cough had since become continuous and the expectoration was abundant and frothy, and at times there had been a great deal of strength and flesh. Vomited frequently; had occasional diarrhea; suffered from night sweats and continued pain in the chest.

Physical Examination: (on admission): Nutrition fair; not very emaciated or anemic. Pancreatic adiposus mod-
erate; weight 120 pounds. Skin, dark and dry; pupils equal and react to light and accommodation; no apparent oral or nasal disturbance. The face as a whole is cyanotic and the malar prominences and the nose are noticeable, the latter being of a definitely globular form. Teeth in fair condition; the upper ones are missing, the lower clean and moist; fine fibrillary twitching; pharynx clear, not congested; neck shows a few palpable lymph nodes, some also found in axilla. Thorax symmetrical, no depressions or protrusions; respiratory movements labored, six in one minute. Heart: Apex beat not seen or felt; right border lies at the midsternal line; left border three inches to left of median line; no murmurs or other abnormal sounds heard. Lungs: Chest expansion equal on both sides, but is slight and accessory muscles are called into play; pleural friction very feeble on both sides; right apex is resonant on percussion, and left apex even more markedly so; numerous mucous, sibilant, and sonorous rales heard all over the lungs; breath sounds are exaggerated and expiration prolonged. The fingers and toes are markedly clubbed and very cyanotic; distal extremities of radius, ulna, tibia, and fibula enlarged, tender, and painful. The extremities are cold; their capillary circulation is stagnant, but there is no edema. The neurological examination revealed no evidence that a diagnosis of complicating hysteria was made. During the nine years which the patient has remained in the hospital numerous examinations of the urine were made. These were almost always negative except that when she had complicating surgical symptoms a small amount of albumin was found. The sputum was almost continually very abundant and of a markedly purulent character; tubercle bacilli have never been discovered, and the predominating organisms appear to be members of the pyogenic group. Examination of the blood, feces, and gastric and duodenal secretions showed but no other complicating conditions apparently independent of the condition for which the case is now reported. Frequent x-ray examinations confirmed the diagnosis of pulmonary fibrosis, emphysema, bronchiectasis, chronic bronchitis, and hypertrophic pulmonary emphysema. Occasionally the admixture of gangrenous material is seen with the typical attacks of bronchial asthma developed; temporarily relieved by the usual treatment, but the attack became progressively more frequent.

In March, 1910, the patient was successfully operated upon for an acute appendicitis, and at the same time a ventro-suspension of the uterus was done. Recovery was uneventful. She had been treated variously; among the more unusual methods may be mentioned exposure of the chest to a x-ray, deep intramuscular injections of coagulating radium, intravenous injections of ephinephrin, subcutaneous and intra-articular injections of chromic sutures, etc. Only temporary relief was attained by any of the methods employed. In January, 1912, she was successfully operated upon for gallstones. Rapid convalescence took place in spite of the persistence of oxygen open to the skin and asthmatic dispositions. Meanwhile the signs of pulmonary osteoarthropathy slowly progressed, and the pulmonary signs and symptoms increased. In April, 1912, the patient was operated upon by Dr. Mackenzie Forbes by an attempt to relieve the embolus in the hip. The details of this operation are herewith indicated. April 16, 1912. Operation. Incision parallel to right border of sternum. Exposed second, third, and fourth costal cartilages. The anterior layer of the perichondrium was reflected outward as far as the costochondral junction. The posterior perichondrium was then separated, and about one and one fourth inches of the intervening cartilage removed. The resections were made with a scalpel, with the exception of the fourth, where the bone cutting forceps were used in removing a small portion of the rib with the cartilage. The anterior layer of the perichondrium was separated from the parietal pleura, and then reflected over the sternal end of the resected cartilage, where it was fastened with two or three fine chromic sutures. The overlapping ends of perichondrium were excised. After bleeding was controlled the pectoral muscles were united by chromic and plain gut, interrupted sutures; the skin with silk and catgut. No drainage. The same procedure was repeated on the left side. The anterior and posterior third costal cartilages were excised. The cartilages on the left side were found considerably enlarged and thickened; a simple dressing and bandage applied. As each cartilage was removed the underlying pleura was seen to retract markedly with each expiration. The patient seemed to breathe easier and took the anesthetic more smoothly. The cyanotic appearance of the mucous membrane changed to a pink color. Since this last operation great improvement in the breathing and in the severity of the asthmatic attacks had taken place. The respiratory movements were more free, but the patient still presented a typical picture of this syndrome. Under hospital discipline the hysterical manifestations had greatly decreased.

(The to be concluded.)

THE SURGICAL TREATMENT OF MONARTICULAR RHEUMATOID ARTHRITIS OF THE HIP.*

BY A. MACKENZIE FORBES, M.D.,

Montreal, Canada,

Surgeon in Charge, Children's Memorial Hospital; Surgeon in Charge, Orthopedic Clinic, Montreal General Hospital.

One of the most serious affections of the hip joint is that which is known as osteoarthritis, hypertrophic rheumatoid arthritis, morbus coxae senilis, or monarticular rheumatoid arthritis. This is a rapidly deforming disease, and during the progress of the deformity which is due to it the patient is continually subjected to pain, especially on movement. The proper treatment of this disease has been a subject of debate since the early days of the history of medicine. There are many who still hold the view that nothing can be done to relieve this affection. This view is held not only by physicians and general practitioners, but a prominent surgeon recently expressed the same view.

One of the earliest suggestions of modern surgeon was to excise the femoral head. This procedure fell into disrepute for two reasons; first, excision of the femoral head is supposed to be accompanied by great shock; second, after excision the neck of the femur was supposed to slip up over the acetabulum onto the ilium and an unstable and painful joint was said to have resulted, in very much the same way as an unreduced congenital dislocation at this joint is said to be accompanied by increasing pain, as the weight of the patient increases after the advent of puberty.

A group of American surgeons then suggested *brise-ment forcé in order to secure movement, or increased movement, at an ankylosed or rapidly ankylosing joint. This treatment did not succeed. Forced manipulations of an already inflamed or diseased joint caused increased inflammation and increased outpouring of bone.

An arthrodesis at this joint was then suggested. This operation was improved and popularized by Albee, of New York, and up to recent years, this operation was considered with greater favor than any other by the most eminent surgeons who had interested themselves in the affections of bones and joints, but to-day it is fair to ask whether it has not been superseded by the procedure about to be considered.

I think that it was two or three years ago that Baer, of Baltimore, began once again to excise the head of the femur for this affection. Synchronously with his work the same procedure was being advocated in the Montreal General Hospital. Dur-
ing these years this procedure has been under discussion and I, personally, have had the honor of discussing it with some of the most famous surgeons in this and the old country. The same objections have now been brought up against it that caused this operation to fall into disuse some years ago, but experience has proved that these objections are without foundation. The statement that the neck of the femur will slip up onto the ilium has been proved to be untrue, if the operative procedure has been performed with sufficient care. It is not necessary to take the head and the greater part of the neck away. The anatomical head itself is all that is necessary to remove; it is best to leave as much of the neck as possible. Then the neck should be replaced into the acetabulum and the patient kept with the lower extremity in a position of extreme abduction for at least six weeks in an endeavor to form a new fibrous head over the incised neck. The objection to the seriousness of the operation, because of the fact that great shock is experienced at the minute of the evulsion of the head from the acetabulum, can be guarded against. With increased experience this operation can be performed with very little hemorrhage. Hemorrhage, if not the cause of shock, is certainly often

Forbes's evulsors used in operation of arthritis of the hip.

the forerunner of shock. It is perfectly true that manipulations about the head of the femur are often accompanied by undesirable symptoms, but these can be guarded against by care and precaution. Baer, of Baltimore, presented recently a series of cases in which this operation had been performed. These patients were shown to the members of the Intercural Orthopedic Club. The results were seen to be so good that not one member suggested the use of an Albee immobilization operation in preference to the excision advocated by Doctor Baer. The operation as I perform it may now be described:

The incisions used are those recommended by Doctor Brackett, of Boston. The first extends from the anterior superior spine posteriorly to the superior extremity of the great trochanter. The second runs down over the external surface of the femur for about three inches. At the junction of the first incision and the second incision a third incision is made running in a direction posteriorly for about two or three inches. The flaps formed by these incisions are then dissected away from the deep fascia. This exposes the great trochanter covered by the vastus externus muscle. With a chisel about the width of the great trochanter this prominence with the attached muscles is detached from the shaft of the femur, after the method first

suggested by Mr. Robert Jones, of Liverpool. The soft parts, including the muscles, are elevated by blunt dissection both anteriorly and posteriorly from the neck of the femur to the acetabulum. Between these soft parts and the periosteum both anteriorly and posteriorly as well as superiorly are inserted the evulsors, which have been recently prepared for me by my friend Dr. Rupert Dorman. Until the capsule is perforated anteriorly, posteriorly, and superiorly. These evulsors are carried around the internal surface of the acetabulum detaching the capsule in all parts from the acetabular rim. The instruments used in this stage of the operation are very similar in shape to an ordinary tack lifter, i.e. from a handiwork a straight shank curved at the end and terminating in a spoonlike extremity. They are blunt and strongly made of carefully prepared and nonbrittle steel. By means of manipulations of the lower extremity in the hands of an assistant and by a prying action with the evulsors, already described, the head is thrown out from the acetabulum by the leverage action of these instruments whose fulcrum, of course, is the acetabular rim. When the head has been removed from the acetabular cavity the aneurysmlike needle—a modification of that originally suggested by McEwen and used for this purpose by Mr. Robert Jones—is inserted around the neck of the femur, and a Gigli saw carried about the anatomical neck as near as possible to the head. The head is then removed by means of this saw. The acetabular rim is then examined and all osteophytes removed from it. The acetabular cavity will often be found to be extraordinarily deep. All hemorrhage being controlled, the neck of the femur is then manipulated into the acetabulum, the great trochanter is replaced in its normal position and fastened there by means of a wire nail. The deep muscles are sutured as tightly as possible about the bone in order to maintain the neck, from which the head has been sown, in the position once held by the head. The lower extremity is strongly abducted, thus jamming the neck into the acetabulum and assuring this position, and the extremity is encased in a plaster of Paris spica bandage. The extremity is maintained in this position for at least six weeks before either active or passive motion is permitted.

485 Guy Street.

ROUTINE SCHOOL DISINFECTION.

BY J. T. AINSLIE WALKER,
New York.
Fellow of the Royal Society of Medicine, Fellow of the Chemical Society, etc.

As the writer was compelled at the last moment to forego the pleasure of hearing and participating in the discussion on Dr. Charles V. Chapin's paper on School Disinfection, read before the recent School Hygiene Congress at Buffalo, he welcomes this opportunity of commenting on the following characteristic utterances of Doctor Chapin in the paper in question:

1. It is, however, clearly shown by figures derived from various cities that there is no real correlation between these diseases (measles and scarlet fever) and school attend-
y, but rather between them and the seasonal temperature. Detailed study of cases also shows that very few cases of scarlet fever and diphtheria are contracted in school.

2. The danger of infection by breathing in floating diphtheria germs derived from saliva deposited on the floors and woodwork is certainly nil.

3. Careful observation shows that persistent fomites infection is of little moment in dwellings and hospitals, and that terminal disinfection after scarlet fever and diphtheria may be safely omitted.

4. There is no massive infection in schools.

Doctor Chapin would probably find it difficult to quote authorities in support of any of the foregoing statements, but there is no lack of authorities against them. Murphy, in 1894, and Goldsmith, in 1907, published figures which clearly showed that there is a very real connection between school attendance and the spread of scarlet fever (Lancet, June 29, 1907), and the Bulletin of the Chicago School of Sanitary Instruction for August 30th contains the following:

<table>
<thead>
<tr>
<th>Active Cases of Contagious Disease.</th>
<th>Existing.</th>

</table>

From this it will be noted that there was a quite startling reduction in both measles and scarlet fever during the holiday period between June 28th and September 2nd, which is at least very strong presumptive evidence against Doctor Chapin's contention. Kingsford, of Liverpool, says: "Inquiries made during the years 1909 and 1910 elicited the somewhat surprising information that in only 1.5 per cent. of the school cases was there a history of a recent previous case in the house. Consequently, where there is a susceptible school child in the family, it is found in practically every instance that this child is the first to contract the disease and is the one chiefly responsible for handing it on to the younger members of the family who do not attend school. . . . The investigation into the cases of whooping cough occurring during 1910 showed that previous cases at the homes were discovered in only twenty-seven instances, or 0.8 per cent. of all cases, so that in this disease also, home infection is of little account with respect to the infection of school children." (Medical Officer, May 25, 1912.)

As regards the second statement, until Doctor Chapin can prove that Bacillus diphtheriae is not the causal agent of the disease, his assertion that the germs may be inhaled with impunity when they have been "deposited on floors and woodwork" is not likely to appeal strongly to medical men.

The first part of the third statement can be, and repeatedly has been refuted both by observation and actual experiment. Shackleton relates that on one of his polar expeditions some articles of clothing were taken from a chest which had not been opened from the start of the expedition three months before (and which consequently had no opportunity of becoming infected during the latter period), and distributed among six members of the party, in four of whom within thirty-six hours septic sore throats developed.

Having regard to the fact that the party had been living in the frozen regions for the greater part of the period mentioned—i. e., away from all other possible sources of infection—and were at the time in robust health, this incident in itself proves conclusively that infection can readily be transmitted by means of fomites. The writer has never heard or read of any experiment having been carried out to prove Doctor Chapin's argument. The second part of this statement has been dealt with elsewhere.1

The fourth statement may be answered by another, by Newsholme, medical officer to the English Local Government Board: "Infectious diseases are caught in the streets only with great difficulty, and this may be described as retail infection, as against the wholesale infection of the schools." (Report of Consultative Committee upon School Attendance.)

As regards the whole question of school infection, it would be easy to quote an overwhelming mass of evidence in opposition to Doctor Chapin's contention that school attendance plays an unimportant part in the spread of infection: "We invite, may we require that children shall attend the schools. Shall we then insist upon their spending most of their waking hours in a disease laden atmosphere?" (Dr. Frank Allport, Interstate Medical Journal, July, 1913.) "Dust of previous days, stirred up and kept in circulation on subsequent days by the movements of the scholars, is capable of conveying disease in many forms." Dr. Henry Kenwood, Chadwick professor of hygiene, University of London, The School World, September, 1908.) "The school child undoubtedly contracts many of its infections in the schoolroom. . . . An unventilated, overheated schoolroom is an incubator for disease germs and a destroyer of physical and mental efficiency." (Bulletin of the Chicago School of Sanitary Instruction, March 29, 1913.) "The organic contents of school dust show that it may be a source of specific disease." (Dr. James Kerr, school medical officer, London County Council, Public Health, November, 1909.) Professor C. E. A. Winslow, in a series of interesting experiments, obtained 22,700 acid forming streptococci to the gramme from an average of nineteen samples of dust taken from New York schoolrooms. (American Journal of Public Health, September, 1912.) Sir Shirley Murphy, medical officer to the London County Council, in a paper communicated to the Second International Congress on School Hygiene, points out that "School attendance concerns the general health, for it means an increase of infectious disease." (Lancet, August 10, 1907.) Professor Winslow, in his Health of the Worker, says: "The worst kind of filth that can get about in a room is spit. Spit may contain the germs of consumption, diphtheria, tonsilitis, and many other diseases, and careless spitting is one of the best ways of spreading them from one person to another." In regard to the need for disinfection, the following authorities may be quoted:

"The entire building should be kept thoroughly cleansed by frequent disinfection." (Dr. Frank Allport, Interstate Medical Journal, July, 1913.) "No one who is conversant with all the facts will dispute the contention that the periodical disinfection

1Medical Record, July 12, 1913.
of school premises is an important branch of school hygiene which is often culpably neglected." (Dr. Henry Kenwood, Chadwick professor of hygiene, University of London, The School World, September, 1908.) "The use of a good disinfectant will destroy all infectious material." (Dr. J. Halley Meikle, medical officer to the Edinburgh School Board, Medical Officer, January 22, 1910.) "It appears certain that isolation and disinfection as practised in the smaller communities of Michigan reduce the cause of contagious disease in round numbers from forty-five to ninety-five per cent." (Doctor Chapin, of Providence, R. I., Bulletin of the North Carolina State Board of Health, August 1913.) N. B. The diseases referred to are typhoid fever, diphtheria, scarlet fever, measles, and smallpox. "To cleanse a schoolroom properly, it is necessary to destroy the germ life as well as to remove the visible dirt. This is why periodic disinfection is necessary even when no known infectious disease has been present." (Memorandum of Scotch Local Government Board.)

Doctor Chapin's views, as expressed above, are in keeping with his earlier and still more startling assertion that disinfection after tuberculosis is unnecessary. That any health officer, and particularly one of the standing of Doctor Chapin, should be willing to commit himself publicly to such a view is to be regretted. It is quite difficult enough as it is to induce the public to take adequate precautions against the spread of communicable disease, and if they have, or ever believe they have, authority for ignoring an essential precaution against the most deadly disease with which they are menaced, the eradication of that disease must be rendered appreciably more difficult of attainment. Is it not high time that some authoritative ruling should be issued not only as to the need for disinfection after communicable disease—and particularly after consumption—but also as to the most approved method of carrying it out?

WHITEHALL BUILDING.

EPITHELIOMA OF THE LOWER LIP IN A WOMAN.

With the Report of a Case.

By Fred Wise, M.D.,

New York.

Chief of the Dermatological Clinic, Beth Israel Hospital; Assistant Physician in Dermatology, Vanderbilt Clinic (Medical Department, Columbia University).

In the female sex, epithelioma of the mucous surface of the lower lip is a rare occurrence; very few instances have been reported in this country. Ericksen (1), of London, a surgeon who has had many years' experience and a wealth of clinical material at his disposal, writes: "I have never met with a case of epithelioma affecting the lower lip of a woman." Mazeau (2), in an essay on epithelioma of the lower lip, says: "The male sex alone pays tribute to epithelioma (of the lower lip); women, even those using tobacco, remain unpunished." Bulkley and Janeway (3) reported 400 cases of epithelioma of the skin and lips in both sexes; of these, thirty-two affected the lower lip, all in males. No mention is made of the disease in the lower lip of females. In Dugue's (4) essay on this subject occurs this passage: "We have always noted the extreme rarity of epithelioma of the lower lip in women. Ericksen stated that he had never seen one. A certain number of such cases are, however, on record. In 1892, the British Medical Journal published a series of cases, the diagnosis having been confirmed by microscopical examinations. In a case published by Herbert Barclay, a woman who was in the habit of smoking a pipe, was afflicted with the disease in the lower lip." Dugue mentions Fricke's figures—one epithelioma of the lower lip

Fig. 1.—Epithelioma of the lower lip in a female.

Fig. 2.—Superficial squamous celled epithelioma. (Low power.)
in women, to thirteen in men—and says that, although many authors state that women are immune to the diseases in this locality, such is not really the case. As to why the lower lip is rare in the female, Dugué believes that the relative absence of irritative agents, such as tobacco, alcohol, trauma, etc., may be the negative etiological factor.

W. Roger Williams (5), a British surgeon, reported upon 352 neoplasms of the lips, of which number 340 started from the lower lip; of these 340 cases, 320 were epitheliomata; of the latter, 326 occurred in the male, only three in the female (that is, less than one per cent.). Theodor Fricke (6), from the Göttingen clinic, has published some very interesting figures on the subject. He collected statistics from five cities in Germany, including therein the records of 1,338 cases of epithelioma of the lips in both sexes. He found that the disease occurred nineteen times more frequently on the lower than on the upper lip, reckoning both sexes together. Of 1,264 cases of epithelioma of the lower lip, 1,174 were in men; ninety (7.2 per cent.) were in women. Of these 1,338 cases, Fricke found that 1,219 (91.1 per cent.) were in males; 119 (8.9 per cent.) in females; while Wörner (7) in 866 cases, found 782 (90.4 per cent.) in males; eighty-four (9.6 per cent.) in females. Fricke calls attention to the remarkable relatively high percentage of epithelioma of the upper lip in women, compared to men; of 782 men with lip cancers, in only seventeen (2.2 per cent.) was the upper lip affected; whereas of eighty-four women, twelve (14.3 per cent.) had the disease in the upper lip.

Loos's (8) statistics are based upon 565 cases of lip cancer in both sexes; 534 of these were on the lower lip, thirty-one on the upper; a ratio of seventeen to one. Of these 534 lower lip cases, 407 were in males, sixty-seven in females (12.5 per cent.). Loos remarks that this percentage in females is considerably higher than the figures given by other authors: that the relative increase of the disease on the lower lip of women, in Bruns's clinic, dates back since 1885 and that he is at a loss to account for this comparative increase in its occurrence.

Hermann Ebel's (9) statistics deal with 199 cases of the disease in the lower lip. Of these, 185 (92.0 per cent.) occurred in men; 14 (7.1 per cent.) in women. This ratio of 13 to 1 agrees with that given by Fricke.

Much stress has been laid on the use of tobacco as an etiological factor in the causation of epithelioma of the lower lip. Loos points out, however, that of 225 patients with the disease in this locality, 119 did not use tobacco in any form,—that is, more than fifty per cent. were abstainers. It is difficult to explain, says Ebel, why, if it be conceded that smoking is a causative or exciting factor, not more than one out of ten thousand habitual smokers become afflicted with malignant disease of the lower lip; on the other hand, many patients having the disease in this locality are abstainers. Of 199 cases in Ebel's clinic, 22 (11 per cent.) had never used tobacco, and this number of nonsmokers does not include the female cases. Wörner, Fricke, Maiweg (15), Regulschi (16), and other authors do not consider the use of tobacco of etiological moment in the causation of cancer of the lower lip.

In discussing the etiology, nearly all authors come to the following conclusions: Women are much less prone to epithelioma of the lower lip, because they are less exposed to injury and irritation due to smoking, shaving, cuts, and blows, etc., because they are more careful than men, as to the hygiene of the mouth. In this connection, Ebel points out that the disease in women is no more common in the Orient than it is in countries where women do not habitually smoke; furthermore, he says that the hygiene of the mouth, in his opinion, plays no role in the etiology, for in the class of women afflicted with the disease, the sanitary measures bestowed upon the mouth are about on a par with that of the men.

**CASE REPORT.**

Mrs. B. K., aged seventy years, born in Russia, applied for treatment at the dermatological clinic of Beth Israel Hospital, early in May, 1913. Her parents and three brothers and two sisters died of unknown causes. The patient was married at the age of twenty-two years and had had ten children, two of whom are living and well. The cause of death in the other children could not be ascertained. The family history regards cancer and syphilis as negative.

The personal previous history was negative, the patient stating that she had always enjoyed good health. She had never used tobacco in any form.

The present illness dates back four months, when the patient first noticed a small papule on the lower lip, to the right of the median line. She soon acquired the habit of picking at it with her fingers. Two months after its appearance, she consulted a physician, who applied "electricity" (7) to the growth, with the result (according to her statement) that it rapidly increased in size, until it had attained its present dimensions, that of a small hazel nut.

The clinical appearance of the growth was that of a typical epithelioma, so frequently seen in the lower lip of men. It had the characteristic induration, the rolled, pearly border, and the discharge and crust formation due to ulceration of its surface. There was no palpable glandular enlargement in the neck or elsewhere. The patient's general health was good and there had been no loss of weight.

The tumor was ablated by Doctor Lewisohn at the Beth Israel Hospital. Microscopical examination revealed a superficial, squamous cell epithelioma.

Through the kindness of Doctor MacKee, the patient was presented before the New York Dermatological Society, at the May, 1913, meeting.

Although I not infrequently encounter cases of diffuse and circumscribed keratoses and warty excrescences on the lower lips of women, the case herewith reported is the first of its kind coming under my observation during ten years' work in the various dermatological clinics of this city and in private practice.
THE TREATMENT OF THE CACHEXIA OF MALNUTRITION.

By Frank Smithies, M. D.,
Rochester, Minn.

From the Division of Gastroenterology, Mayo Clinic.

There appears to be a class of individuals which, clinically, exhibits weakness, languor, pallor, with or without actual anemia, blotchy muddy skin, anorexia, dyspepsia, often associated with vomiting and prolonged constipation. In these patients the deviation from the normal can be attributed to no actually demonstrable cause, even after the most careful clinical scrutiny. The cachexia in this type of case is often extreme and may progress to the death of the individual. It is usually ascribed vaguely to "auto-intoxication," due to constipation, without apparent regard to what may be the initial factor in the production of such constipation. This group of individuals is difficult to successfully treat, whether by surgical procedure for relief from "toxic" substances said to be absorbed from the large bowel, or by purely medicinal or hygienic measures.

On December 18, 1912, there came to the Mayo Clinic an individual like this, in the hope of securing relief from a surgical operation of the "short circuiting" type.

The patient was a Russian Jewess, aged twenty-six, whose height was 5 feet 1 1/2 inches, and who, fully clothed, weighed 60 1/2 pounds. She had previously had an appendectomy performed elsewhere, with a second operation for the relief of adhesions, but without relief of constipation, sour dyspepsia, and cramplike, general abdominal pains. During the year preceding her coming under observation, she had lost in weight more than thirty pounds, was extremely weak, and had gradually become bedridden. Hemoglobin was seventy percent, urine negative, stomach examination showed normal acidity, without retention, with moderate visceroposis, as shown by air inflation of stomach and bowel, and by radiogram.

Perhaps on account of the patient's extreme emaciation, operative interference was not deemed advisable. The patient was referred for medical treatment. In view of the work of Lusk and his associates (1) upon animal calorimetry, and especially that work on the metabolism of dogs following the ingestion of amino acids, it was decided to observe the effects of similar measures in the human. Fortunately there was at this time a man in the clinic who was about to be operated upon for the relief of a "vicious circle" following gastrojejunostomy for duodenal ulcer. From him we were able to obtain gastric extracts of a golden color, which had total acidity of 68, hydrochloric acid 60, and exhibited tryptic and amylolytic activity of more than 10,000 units by the Gross-Fuld and the Wohlgemuth quantitative estimations. More than 650 c.c. of gastric extract were secured from this patient, filtered through fine sterile sand, and several times through double, hydrochloric acid washed filter papers to free from microorganisms, and then preserved in a sterile flask under toluene (Merck). It was our purpose to avail ourselves of the ferment activity of this gastroduodenal juice, in the preparation of end products of digestion upon which to feed our patient.

It will be recalled, that in the digestion of protein by the gastric juice, it is successively converted through the stages of soluble globulin, acid metaprotein, proteose (propeptone) to peptone. Pancreatic ferment further splits this derived peptone to polypeptides, which are then broken up into soluble amino acids, hexone bases, aromatic amino acids (tyrosine, tryptophane) and ammonium compounds. The pancreatic juice may, of itself, bring about all stages of protein cleavage. Upon carbohydrates, the pancreatic juice acts completely from the stage of soluble starch through to malsoe. The villi of the small bowel, and perhaps the duodenum, take up these soluble products, and from them synthesize the tissue and body fluid protein.

We decided to feed our patient on a mixture of split peptone and malse. In order to make the procedure as physiological as possible, we ventured to feed her this mixture by a duodenal tube, metagastrically, e. g., where in the process of digestion such ingredients are normally produced and absorbed, to a saturated solution of Witte's peptone (about five per cent. by weight) in distilled water, was added one per cent. by weight of soluble starch (L'sntner). To one litre of this mixture were added twenty-five c. c. of the filtered gastroudenal extract. This was incubated under toluene at 37°C. for twenty-four hours. A specimen of the mixture acidulated with three per cent. acetic acid, and then tested for free tryptophan, gave the typical rose pink color reaction. The split peptone mixture, tested independently after incubation, had a formol index (method of Sorensen-Schiff) of 250. A duodenal tube was passed upon the patient in the usual manner. Through it, twice daily, were injected in the early progress of the case 100 c.c. and later, increasing amounts up to 1,500 c. c. of the split peptone starch solution. No ill effects were observed. The patient was permitted to eat the same sort of diet on which she had been
previously subsisting, and was not put to bed. The bowels were relieved by an occasional dose of castor oil.

The results of the treatment outlined were so encouraging as to warrant its continuance. There were a steady gain in weight and strength, an increased mental activity, a clearing up of the blotty skin, an improvement in hemoglobin, and an alleviation of the distress associated with constipation. At the end of three months the patient weighed 99½ pounds (a gain of thirty pounds,) and was engaged, after nearly two years' idleness, in her trade of hair dressing. At the end of 4½ months she weighed 114½ pounds (a gain for forty-seven pounds) and was so well physically, that she ceased keeping her appointments for treatment, and had established herself in a little business. She was still constipated. Her hemoglobin had risen to ninety-five per cent., her complexion was rosy, her eyes bright, and her strength so good, that a satchel carrying more than ten pounds was easily carried, as the patient walked between the houses of her customers. Treatment had been discontinued over two months, and the patient remained apparently normal.

The results in this case were so encouraging as to justify further trial with other patients. Digestion of the peptone was later carried on with trypsin instead of the gastrojejunal juice. To the split peptone solution was added maltose in the proportion of five per cent. by weight. This mixture was given metagastrically. It appeared to act very well and caused no disagreeable effects. We have used the procedure on two other patients, both women, with cachexia of the type above described. The details of the cases are reserved for a future report. The patients have progressed in a very satisfactory manner.

Conclusions.

From the results of our work we feel warranted in suggesting this therapeutic procedure to others for the treatment of cachexia, where surgical relief is not available; where nonobstructing vomiting has become more or less pernicious; where stricture of the esophagus or cardia prevents ingestion of sufficient food to support life; where functional estimations show low pancreatic activity; where grave anemia exists, and in the asthenia following extensive surgical operations. Split peptonemaltose solutions are well borne in the stomach, and there may exist-cases where their ingestion through the stomach tubes may prove valuable.

REFERENCE:

PROPHYLAXIS OF INSANITY.*

By H. C. PODALL, M. D.,
Norristown, Pa.

The prophylaxis of insanity is of particular importance to the medical profession, on account of the large number of insane and feebleminded in the institutions of Pennsylvania. In the United States in 1912 there were 250,000 insane; more than eight times the population of Norristown. Hospital statistics show that the insane population in institutions is increasing at the rate of 6,000 patients a year, and about 30,000 new cases of mental disease enter our public and private hospitals for the insane each year.

Heredity and environment play an important part in our life; the influence of heredity begins generations before the child is born, while environment only awaits its entrance into the world to assert its influence. We all know that members of some families have great resistance or vitality, who may have had severe physical illness, trauma, or indulged in excesses without mental symptoms, while other families lack this resistance and show a temporary or permanent mental aberration after a less severe illness. Some rebound from financial, domestic, or other difficulties, their only apparent effect being to spur them on to greater efforts, while to others these difficulties result in depression, suicide, or a flight into an acute psychosis where their wishes are realized in the fancies of the abnormal mental state. Heredity in some mental diseases is more marked than others. The study of the families of those suffering from epilepsy, dementia precox, and manic depression reveals the fact that they belong to strains with mental weakness, individuals whose nervous system cannot stand great stress, and as a result, we have a breakdown.

The great problem before us to-day is not so much to cure the mental disease already developed, as we know that only one fourth of these cases are curable—the other three fourths are the chronic insane that fill our institutions—as it is to recognize the unstable child and adult in whom the psychosis is apt to develop and direct them so that the disease may be prevented.

The world wide movement in the fight against tuberculosis has accomplished much, the percentage of deaths is yearly being lessened, and the campaign against mental disease must be along the same line. The public must be educated by the medical profession; it is only with the full cooperation of the public that results can be best accomplished. In order to achieve success it will be necessary to inform the public regarding the nature and causes of mental diseases, so that it may be acceptable as a disease, and not as a crime or a family disgrace, and receive intelligent treatment.

The family physician in caring for the patient during the onset and early stages of mental disease, should in many cases advise hospital treatment. The recognition of the earliest manifestations of the disease, and its treatment, will determine to a great extent the course and prognosis of the case.

The earliest admission to a hospital is of greatest importance; hospital records show that of those in whom the duration before admission is short the patient's chances of recovery are best. In this country one third of the patients admitted to hospitals for the insane have had their disease more than eleven months. In England, in 1000, eighty-five per cent. of patients were admitted to hospitals for the insane during their first attack. This was

*Read before the Montgomery County Medical Society, June 25, 1913.
directly due to improved standards of care for the insane.

Some of the efforts to prevent mental disease have been along the lines of eugenics, for which sterilization, regulations of marriage contracts, and the improvement of the public health have been advocated. At present eight States have laws for sterilization: Indiana, California, Washington, Connecticut, Nevada, New Jersey, Iowa, and New York. Of these, only two States have put the laws into effect. Other States have advocated similar laws. The State of Pennsylvania has a bill before the legislature for a similar law. Some advocate a certificate of health before contracting marriage. The public is not yet ready to accept the responsibility for such drastic measures. Only occasionally do we hear of ministers refusing to marry isolated cases where known ill health exists. The main issue to-day is to collect and study facts regarding the unfit, and teach the people the importance of these facts.

In every general hospital and in the practice of the general practitioner will be seen an occasional case of pneumonia, typhoid fever, cardiac, or renal disease in which the patient will develop mental symptoms, either temporary or for a longer period, requiring attention. The question will arise, should these patients be cared for at home or sent to a hospital for the insane, as in most cases they cannot be cared for in the wards of a general hospital?

In some cities psychopathic wards are attached to general hospitals and patients are accepted for observation and treatment, until it is determined whether or not a hospital for the insane is their proper place. They afford treatment for acute mental diseases in the early and most curable stages, thus assuring a larger percentage of recoveries. They provide facilities for research and the scientific investigation and prevention of mental disease, and thus lessen the accumulation of the chronic insane.

It has been shown that a large number of cases of dementia precox result from improper training in early life, especially in the years of character formation. In children particularly we find many examples of psychopathic characters. It has been shown that uncontrollable anger may become a mania, and fear and suspicion increase to delusions; these may be temporary, not necessarily ending in insanity. The establishment of special schools for feebleminded and backward children under proper medical supervision would withdraw the constitutionally inferior from competition with the normal child, and give them an opportunity to develop along the lines of physical rather than of mental training.

We should not spoil a good laborer by trying to make him a poor professional man, by forcing him beyond his mental capacity. Let me illustrate this point by a few cases from our experience at this hospital.

Case I. R. W. K. (1876). A young man from a family in which mental disease was present, had an attack of typhoid, following which he had hallucinations for several weeks, and convalescence was delayed. His brother also had the same condition following the same disease. Both apparently recovered. It is evident this was an indication of an unstable nervous system. This young man persisted in taking up a long course in one of our universities, and in his junior year a psychosis developed which necessitated hospital treatment with little encouragement for recovery.

Case II. E. A. L. (1898). From the family history we find the father used alcohol to excess. The mother had a nervous temperament. The patient had never been of a sociable disposition, always exclusive, never associating with other boys or girls and not inclined to any amusements. He took up the study of law and after a good deal of difficulty with his studies passed his examinations. About one year later began to show symptoms of a psychosis, and is at present a patient in this hospital.

Case III. M. J. (1769). Maternal grandfather and uncle were insane. Patient graduated from high school at seventeen years of age; then entered one of the medical schools at Philadelphia. At the end of the first term he failed at the examinations in one half of his studies. In the fall term he went to Baltimore, Md., and entered a medical school. While there he wrote to his father, stating that he had the prodromal symptoms of some mental disease. He continued his studies, however, until the end of the term. He failed to pass in all of the examinations, and shortly after was committed a patient to this institution with a hopeless prognosis.

Alcohol and other excesses contribute largely to the causes of insanity. We realize that all persons do not react the same way to alcoholic indulgence. Some people go through a long, useful life with a daily use of alcohol and show no mental symptoms, while in others indulging to a less extent an alcoholic psychosis develops. We know that alcoholic indulgence in some produces epilepsy, in some hallucinations, and in others delusions of a paranoid type, showing the different effects of the same cause.

Paresis, which causes the commitment of about eight per cent. of male and two to four per cent. of female patients to insane institutions in the United States, is due to infection with syphilis.

In some European cities (Berlin and Munich) the paretics average thirty-five to forty-five per cent. of male admissions. The proportion of male and female paretics is about one to six. The disease is more prevalent in large cities and manufacturing centres, and less so in farming communities. For many years past it was thought to be a parasyphilitic disease of the brain resembling locomotor ataxia, which affects the spinal cord; that is, in a small proportion of persons infected with syphilis, paresis would develop in ten or twenty years following infection.

The recent work of Nojichi and Moore has demonstrated the presence of Treponema pallidum in the tissues of the brain, which shows that it is only a late manifestation of syphilis.

In women the effects of childbirth, especially when the births follow closely upon each other, the infection that may occur during the puerperal period, and the exhaustion of tuberculosis and other acute or chronic diseases, and surgical operations often precipitate a mental breakdown which might have been avoided if the physical health had been more carefully preserved.

In a small proportion of imbeciles we find an acquired type whose mental enfeeblement follows an infectious disease like scarlet fever or diptheria, which was probably due to encephalitis or meningitis though they were mentally normal be-
fore the onset of the acute disease. These cases may be classed as examples of arrested development rather than imbecility. This sequela may or may not be the result of improper treatment, but it is a possibility that we should bear in mind.

About five per cent. of the cases develop after an exhausting physical disease. They have been classed as exhaustive, or infective exhaustive, psychoses, for example: the clerk, stenographer, or seamstress, attempting to do more work than is possible, may resort to stimulants to spur the lagging energy. The presence of tuberculosis or other disease precipitates physical failure, and with it a fairly characteristic train of mental symptoms, which fortunately disappears in most cases as physical health is restored by careful treatment or nursing.

There is another type of cases which is of sufficient interest to mention in this connection. The reports of the German, English, and American armies show that a uniform average of the recruits do not make soldiers because they cannot stand the rigid discipline that is necessary for this calling. They become insubordinate, break the rules of the army, and would be subject to punishment if it was not realized that their conduct was only the result of their mental deficiency.

We also receive patients from the penitentiary and other similar institutions in whom, after a few weeks or months of imprisonment, a psychosis develops closely allied to hysteria with apprehension, irritability, hallucinations, and ideas of persecutory nature; these patients as a rule recover promptly, when placed in hospital environment, and are often accused of malingeriy, but they are only of that class of mentally deficient who react to their environment by being attacked with an acute mental disease.

CONCLUSIONS.

To summarize, let me say that defective heredity is an important factor in the causation of mental disease, being found in about eighty-five per cent. of all cases.

Alcohol and drug addictions furnishes twenty to thirty per cent. of the cases. In Vienna among the male insane thirty per cent. were found to be alcoholics, and among women only four per cent. were alcoholics. Male alcoholics greatly predominate.

Paresis which is due to syphilis is found in all classes and professions. It occurs more frequently in male and is to a great extent preventable.

Dementia praecox furnishes fourteen to thirty per cent. of all admissions to insane institutions. The recognition of the earliest symptoms of the disease and proper treatment is essential.

Manic depressive insanity, one of the most important forms of mental disease, comprises twelve to twenty per cent. of admissions to insane hospitals.

Exhaustive childbearing, infectious diseases, and the strong competition in the struggle for existence, are important factors in mental breakdown, and any means that would tend to eliminate any of these causes would go far to prevent mental disease.

OBSTETRICAL EXPERIENCES OF A COUNTRY DOCTOR.

By C. L. Sigler, M. D.,

Pinckney, Mich.

There is perhaps no phase of a general practitioner's work that calls for more quickness of thought and action than his obstetrical cases, and in illustration I wish to briefly describe three that fell to my lot in one day not many months ago.

The first one was in answer to a hurry call some nine miles in the country, and I had no knowledge of the patient until I was at her bedside and found her in a terrific convulsion. I ascertained that she was between three and four months' pregnant with her first child, and had been seized with a similar attack some forty minutes before they called me. Fortunately I had my obstetrical kit with me, and I gave her a few inhalations of chloroform, which had the effect of relieving the spasm, but left her unconscious. An examination revealed no dilatation of the cervix, and a pulse of 160. I immediately gave her thirty drops of tincture of veratum viride, and repeated the same dose in fifteen minutes; which had the effect of bringing the pulse to 120. In the meantime I had telephoned for Dr. Wylie of Dexter, and upon his arrival we forcibly dilated with our fingers and removed the fetus and membranes. The patient had one mild convulsion during this operation, which necessitated a small amount of chloroform, and at its completion we gave her another twenty-five drops of veratum viride, and the patient was unconscious less than one hour after this, consciousness was returning, and the pulse was well under 100, and of good quality. As no urine was being secreted, the patient was placed in a hot pack until in a profound perspiration. The urine was very scanty the next day, and completely solidified upon boiling, but after a few days on milk diet, and with one grain of sodium nitrite every three hours and one two hundredths of a grain of nitroglycerin at the same interval, the albumin became merely a trace with the blood pressure, which had been around 150 mm. Hg, fell within a few weeks to 115-120 mm. Hg.

I wish to say just here that in the case of eclampsia, no matter what the stage of pregnancy is, I never feel safe until the uterus is empty, and have never been sorry that I emptied it at any period. In one case I left it until the seventh month, so as to get a live child. This was successfully accomplished, but the mother never got over the injury to her kidneys, and died of chronic Bright's disease inside of four years. In all cases where I have emptied the uterus immediately upon the appearance of convulsions, or very grave signs of kidney involvement, the mothers are alive, and in more than one instance have gone through labor successfully since.

Upon my return home from this case I was called to see Mrs. W. K., a primipara, aged twenty-four years, who had had a ventrofixation some two years before. The fundus was firmly fixed about midway between the pubes and the umbilicus, and could not be barely reached with the tip of the finger, and was pointing upward and backward toward the lumbar region. Under chloroform the whole hand was introduced into the vagina, and an effort made to partially replace the uterus, so that delivery might be accomplished; but this proved to be totally out of the question. Doctor Wylie was again summoned, and we had the nurse prepare our instruments and patient, and with the able assistance of my father, H. F. Sigler, we operated as follows: An incision was made from about an inch above the umbilicus to the pubes, and after severing the adhesions made by the previous operation, a trial was made to replace the uterus, but its size rendering the impossible, an incision was made longitudinally in the posterior wall of the uterus. The child was then grasped by the leg and quickly removed, and the uterus seized between hot packs, which caused a prompt contra-
tion, and the placenta was removed by the same incision. There was but very little hemorrhage, and the uterine incision was quickly closed by two rows of twenty day chromic gut, and the abdominal incision closed in the usual manner.

Fate not considering two enough for one day gave me another in the case of a primipara, at term in which the head refused to engage. The patient had been having some pains for twenty-four hours, but as they had not been very hard, had waited for me until about four o'clock in the afternoon. At this time the cervix was fairly dilated, pains strong and coming every five minutes, presentation left occipitoanterior. After waiting an hour I quieted the patient with a sedative hypodermic tablet, and left instructions to call me when the pains again became severe. About 7 o'clock, and at this time I found the conditions practically unchanged. The pains were hard and forcible, but the patient was becoming exhausted, and all were anxious that I should "do something." After waiting an hour more, and finding absolutely no progress, I had to choose between high application of the forceps and version. Feeling that the former was the least to be dreaded, I easily applied my Elliott forceps, and in one half hour delivered a lusty thirteen pound boy. The forceps were removed as soon as the head was well down on the perineum, and one or two good pains finished the delivery, with only a slight perineal tear, which was immediately repaired with chromic gut.

All these patients made good recoveries, the first being kept on a semiliquid diet for several weeks, and the bowels kept well open with salines. At the present time she is apparently normal, with normal urine and a blood pressure of 115 mm. Hg. The ease with which Cesarean section is performed should cause it to take the place of many obstetrical procedures sometimes used, and would many times be the means of saving both mother and child. In one case of placenta previa in which I lost both mother and child (the only mother lost, by the way, in some 500 cases) I believe both would have lived had I delivered in this manner. In one case of acephalic monster the placenta was removed before the birth of the child and without an ounce of hemorrhage during the whole delivery. In one case of hydrocephalus the cranial vault was absent, and the skin stretched so thin that it was taken for a hydramnios, and was easily ruptured with a probe and an immense amount of water evacuated. The fetus had apparently been dead for some time, being macerated and fetid. Another patient was delivered of a live child at full term, and in the same sac there was a dead three months' fetus, the mother giving a history of having had symptoms of threatened miscarriage at three months. In over 500 cases there has been but one pair of twins, one case of cleft palate, two of harelip, and one extra-uterine pregnancy in the entire series. This was not diagnosed until after rupture had taken place, but the patient recovered without operation, although an immense hematocoele formed and she nearly died from the hemorrhage. Operation was refused, and now, after six years, there are still remains of the hematocoele. Two Cesarean sections have been necessary, one for contracted pelvis and the other as related above, both resulting in living mothers and children.

There has been no complete laceration of the perineum. Perineal tears are immediately repaired, using chloroform with twenty or thirty day chromic gut. Ergot is never used until after the birth of the child, and sometimes not until after the removal of the placenta. In the latter case it is my usual custom to use aseptic ergot hypodermically. Chloroform is almost always used, and is discontinued upon the delivery of the head. The placenta is never extracted until good contractions are produced, and then by the modified Credé method. Forceps are not often used, and I have been more often sorry for using them than for not. Pittuitrin has been used in a few cases, and seems to be useful. Gloves are not worn in ordinary cases. At the first bath the child's eyes are washed with boric solution, and in all suspected cases silver instillations are made.

These methods are by no means given to guide others who may have had greater experience or better results, but that others may profit by my mistakes, as well as from what few good things I have accomplished in this soul trying and poorly paid branch of the country doctor's work.

Therapeutic Notes.

Primary Suture of the Bladder.—H. A. Moore, in the Urologic and Cutaneous Review for March, 1913, asserts that the methods of closure of the bladder commonly employed after suprapubic cystotomy are, in reality, relics of the darker ages, and strongly emphasizes the advisability of effecting immediate closure in cases of suprapubic prostatectomy where the cystitis is not too great, in many cases of suprapubic lithotomy, in suprapubic cystotomy for retrograde catheterization of impassable urethral stricture, and after the removal of benign and many malignant growths, in cases where hemorrhage is not excessive.

Air distention of the bladder should be practised, both to keep any existing infection at a minimum, and to force the peritoneum out of the space of Retzius. A longitudinal incision of medium length is best, the peritoneum being rolled up from the anterior bladder wall when the prevesical fat is reached.

After the intravesical work is complete and hemorrhage controlled, the bladder neck should be divided and a slight incision made at the meatus if this orifice is too small to admit the large catheter—No. 30 French—necessary for drainage. Such a catheter is large enough to permit the removal of clots by aspiration. It should protrude into the bladder about half an inch and be anchored to the penis.

The bladder wall should be closed with chromic catgut in two layers, the first of these with interrupted stitches (not penetrating the mucosa) and the second with a continuous suture. The muscles
and fascia are closed in layers with catgut, or with silkworm gut where the bladder is foul, and the skin with silkworm gut.

In some cases the bladder should be carefully irrigated daily with boric acid solution, three or four ounces being used at each irrigation and repeated until a quart or more has been employed. Ordinarily, however, it is preferable simply to give large quantities of water internally. Where an infection is feared drainage from the space of Retzius may be maintained for from twenty-four to thirty-six hours. Usually the patient can sit up in a chair after four days, and the drainage is discontinued in a week.

Treatment of Constipation in Infants.—G. Schreiber, in Paris médical for May 10, 1913, states that constipation in the nursling is generally related to feeding that is defective, either in quality or quantity.

In the breastfed infant the treatment should include regulation of the intervals of feeding, and an increase in the amount given at each feeding, if necessary. Pastry, sweet dishes, spices and stimulating beverages should be forbidden to the nursing mother or wet nurse, and the meats reduced. Green vegetables, cooked salads and cooked fruits should be ordered, and if there is persistent constipation, castor oil or magnesium prescribed.

In the bottle fed infant cane sugar should be replaced by pure lactose and if constipation is not thereby overcome, the sterilized milk should be diluted with one third its volume of boiled water, or replaced by boiled milk or certified raw milk.

In the weaned child, barley flour should be used for the preparation of porridge, cocoa, and all foods containing it prohibited, abuse of milk guarded against, and, at the age of eighteen to twenty months, strained green vegetables, cooked fruits, and compotes ordered in plenty; a quarter of an orange may also be given.

The medicinal treatment of constipation in infants may consist in the use of the following suppository:

- **Gelatini** .................. gr. xii (0.75 gramme);
- **Glycerini** ................

Aqua 

M. Sig.: Introduce in the evening.

Twice weekly an enema of from three to six ounces (100 to 200 grammes) of a two per cent. infusion of marshmallow, or one containing 15 grains (1 gramme) of boric acid, should be given.

To each bottle of milk may be added a teaspoonful of:

- **Sodium citratis** ............. gr. xxx (2 grammes);
- **Aque distillata** .......... .5iv (120 grammes).

Misc.

Or of a solution of sodium sulphate in similar ratio.

Laxatives should be used with great caution in the first year of life. If their use becomes necessary, a teaspoonful of the following may be given in the morning on an empty stomach:

- **Oleolive (pure)** .......... .5iii (100 grammes);
- **Oleol menthe piperitae** .......... gtt. 1.

Misc.

Or, castor oil may be given in doses of forty minims (2.5 grammes) for each year of age, preceded and followed by the juice of an orange. Calomel may be administered, as advised by Marfan:

- **Hydragryi chloridi minus** .................. .5iv (0.05 gramme);
- **Sacchari lactis** ...........

M. et pone in chartulis No. x

Sig.: Two powders a day on five days in each month.

Treatment of Wounds and Denuded Skin Surfaces.—Delanglade, at a recent meeting of the Marseille Surgical Society (Revue de chirurgie, May, 1913), pointed out the disadvantages of the dressings commonly used, moist as well as dry, in wounds covering a wide area of skin—especially burns—and discharging freely. In order both to secure efficient drainage, and not interfere with epithelial proliferation and healing, the author uses silk protective with numerous openings, which, after sterilization by boiling, is applied directly to the open surface, and then covered with an ordinary absorbent gauze dressing. The silk material does not become adherent and can therefore be very easily removed without causing hemorrhage or pain.

Poncet, at the same meeting, recommended a continuous oxygen bath in the treatment of grayish open surfaces with poor tissue vitality, such as are met with, for example, in diabetics. Two oxygen containers are used, one full and the other empty. In the latter an opening is made large enough to admit the limb or stump on which the open area is situated. Oxygen is then admitted around the part, and changed every twelve hours. The treatment is continued for several days and generally gives perfect and very prompt results.

A Formula for Combined Stomachic and Laxative Effects.—Bardel, in Paris médical for April 12, 1913, is credited with the following combination for these purposes:

- **Fluidextracti rhamni purshianae** .......... .5v (20 grammes);
- **Tincture nucis vomicae** ........... .5ss (2 grammes);
- **Aqua laurocerasi** ...........

**Syrupi** ...... { .5ss (15 grammes);

**Aqua destillata** .......... .5iii (100 grammes).

M. Sig.: Three or four teaspoonfuls daily.

Treatment of Amenorrhea.—Paris médical for May 3, 1913, suggests the following prescription for amenorrhea, where rheumatic disturbance of the uterus is believed responsible:

- **Potassii iodidi** .......... .5iv (8 grammes);
- **Vini colchici seminis** .......... .5iv (4 grammes);
- **Syrupi sarsaparillae** .......... .5ss (20 grammes).

Aqua destillata.

M. Sig.: Three teaspoonfuls a day.

Preservation of Surgical Instruments in the Tropics.—J. Ganon, in Archiv für Schiff- und Tropen-Igiene for March, 1913, describes a simple and inexpensive method of keeping instruments in good condition in tropical climates. After the instruments have been thoroughly dried they are immersed in a solution of petrolatum dissolved in gasoline or benzine. The volatile constituent in this solution soon evaporates off, leaving a thin protective stratum of the petrolatum adhering to the instruments.

THE CAUSES OF INFANT MORTALITY.

At the opening meeting of the English speaking
conference on infant mortality held, on August 4th
and 5th, in London, the address of Mr. John Burns,
president of the British local government board,
was so replete with sound common sense excellently
expressed, that although a great deal of the sub-
ject matter necessarily treated the question from
the British standpoint, yet much of what he said
might be applied to infant life and mortality in
all lands, and thus cannot fail to be of interest to
everyone concerned in the campaign now being
waged for the saving of children's lives and for
the conserving of their health.

Referring to the influence of city life on child-
hood, he said that, apart from money, from the
means of commanding physical comforts, the
modern conditions of city life were inimical to
childhood, housing, atmosphere, aggregation, food,
noise, the stress of city life, even education when
undertaken too early. It was also pointed out that
a fruitful cause of infant mortality in Great
Britain is the fact that mothers work away from
home too much, a state of affairs which prevails
also to a considerable extent in some of the indus-
trial centres of America. As conclusive proof that
this is so, it was shown that in those parts of Great

Britain in which mothers worked in factories most
largely, the infant mortality was more than twice
greater than where mothers lived at home. Referring
to the diseases of maternity and paternity, the
speaker said that these diseases should be con-
sidered more seriously. We ought to learn why
twenty-three per cent. of the deaths from cancer
among women occurred in the genital organs.
Sexual diseases should be looked into more closely,
in regard to which society showed a prurient
delicacy which was dangerous, but he was glad
to be able to state that the local government
board had in preparation a report which he hoped
might be of assistance to medical men in their in-
vestigations. However, he deprecated a stampede
on the matter.

Mr. Burns announced himself no believer in the
theory that the survival of the fittest was best for the
race, or as he put it, he did not belong to the
"better dead" school, but was solidly convinced
that the lives saved by lower death rates meant
healthier lives for the survivors generally. The
government regarded the health of the people as
the supreme law, and however much their trade,
commerce, and wealth might increase, however
much their material supremacy in the world might
grow, all these things were as nothing unless they
had clean and happy homes in which mothers could
live decent lives.

The speaker laid special emphasis on the truth
that the life of the infant is now measured in city
communities perhaps more by its prenatal condition
than by its postnatal environment after it has been
healthily born. Indeed, all those who read papers
at the conference were as one in insisting upon the
point that it is of vital importance that the mother
should be well nourished and cared for during some
months before her confinement.

THE RELATION OF THE PITUITARY TO
GROWTH.

While Pierre Marie first called attention to the
relation between acromegaly and the pituitary,
and Sternberg found that forty per cent. of the patho-
logical giants had enlargement of this organ, there
is still considerable difference of opinion as to the
manner in which the overgrowth is produced. The
anterior lobe may be found edematous or hypertro-
ephic; according to Lewis the organ is the seat of an
adenoma in the majority of cases. As to the
manner in which the pituitary causes excessive
physical development, there is still considerable
difference of opinion. It may be due to stimulation
of the thyroid or adrenals through problematic fibres
arising from the pituitary, or to an excess of the
problematic secretion of the anterior lobe. The latter view is the preponderating one at the present time.

Metabolism experiments in animals after the administration of pituitary gland, as exemplified by the researches of Thompson and Johnson, Malcolm, Franchini, and Benedict and Homans have shown sufficient variation to annul the value of the findings. Feeding experiments with gain of weight as standard have also furnished but little reliable information, although those of Shaefer have seemed to indicate some degree of influence, though they were too few to eliminate all elements of error, so common in experiments of this class.

The recent researches of Lewis and Miller (Archives of Medicine, August 15, 1913) seem, however, to have afforded results which warrant definite conclusions, their experiments having been conducted in such a way as to exclude all serious causes of error. The experiments were numerous enough; the amounts of gland administered were sufficient to give results, since they were equivalent, relative weight being taken into account, to 230 grammes given daily to an average man. On the other hand, the amounts were not sufficiently large to awaken deleterious effects. While it is possible that the digestive fluids may destroy the active substances, and feeding preparations by the mouth cannot be deemed analogous to the effects of a secretion supplied normally by one or more ductless glands, the fact remains that the tests showed that "neither anterior nor posterior lobes had any effect on the weight or growth of the animal."

YOUNG CHINA AND LEPROSY.

Dr. J. J. Matignon, a well known French army surgeon, former attaché of the Legation at Pekin, in Archives de l'anthropologie criminelle et des sciences pénales, Paris, 1913, xxviii, pp. 372-375, gives some interesting details of the methods adopted to eradicate leprosy in the city of Nanking, capital of Kiangsu, on the frontier of Tonkin, on the 14th of December, 1912. For some years there had been on the outskirts of this town, a harmless quarantine, or colony, of lepers who subsisted by means of the sale of straw sandals and false hair, begging, and contributions received from the French missionaries. The latter had even proposed to build a small hospital for their assistance, and this project had been favorably regarded by a number of the well to do inhabitants and, as it seemed, by the governor of the province himself. Nevertheless, the young China element immediately set about to defeat this idea, demanding that the Catholic mission would do better to come to the aid of the govern-

ment than to build a leprosorium. The missionaries became uneasy, but were reassured by the governor, who, in the meantime ordered that a ditch, two or three metres deep, be dug on the field of manoeuvres. What follows is taken from a letter from the Catholic mission, published in the Bulletin de l'Asie française, of March 11, 1913:

We were still full of confidence, when this morning, December 14, 1912, we were overwhelmed by the news that the village of lepers was surrounded by soldiers, at day-break, and all of them were massacred. We immediately sent for information and here is the horrible result! More than a hundred soldiers encircled the village so that no leper could escape. Like a herd driven to the slaughter house, they were forced to the manoeuvre field toward the ditch prepared for them, the bottom of which was filled with wood with a ladder arranged for descending into it. One by one, the lepers, their wives and their children were forced to descend the fatal ladder and seat themselves upon the funeral pile. As the word "cha!" (kill!) rang out, the muskets were discharged point blank. Petroleum was poured out in abundance, and a bonfire announced to the city the victory of the liberal party.

It appears that the governor of Nanking, far from disclaiming responsibility in the matter, expressed himself as highly satisfied with the zeal of his subordinates and, in a public proclamation, denounced the lepers "for molesting the villages, ravishing their women, and stealing their money," with the result that rewards of from five to ten piastres were offered about the town for anyone who would locate a leper so that he might be shot. Doctor Matignon compares these atrocities with the doings of the Boxers in 1900 and concludes that the "civilization" of Young China is, at best, only a varnish or veneer. Certainly the Middle Ages even succeeded in stamping out leprosy by methods which were not only more efficient but infinitely more humane.

THE LIMITATION OF BUILDING HEIGHTS.

There can be no question that, from the health standpoint, as well as from various others, the height of buildings in cities should be regulated by law, and the constitutionality of such legal limitation appears to be well established. The deprivation of light and air certainly comes under the head of a sanitary condition, and in building to unlimited heights there is a great menace, as this is an active cause of congestion of population. Conditions around "skyscraper" buildings on windy days constitute a practical nuisance, and cases are not infrequent where accident or death has resulted from the strong wind currents in the neighborhood of such buildings. Then, there is the terrible danger from fire.

Many of the cities of Europe, including all the
great capitals, have long had height restrictions, and this is also found to be now the case in at least twenty-eight important American cities. New York is far behind other cities and countries, and, indeed, has been culpably negligent in regard to this matter. Many years ago the subject was taken up in the Academy of Medicine, and the opinion expressed that the height of buildings ought to be regulated by law in accordance with the width of the streets on which they stand. As a result of the agitation of the matter at that time a law was enacted in 1885 which prescribed that the height of tenement and apartment houses should be limited to seventy feet on streets not wider than sixty feet, and to eighty feet on streets wider than this. Since then various changes in the law have been made, and under the present Tenement House Laws tenement and housekeeping apartment houses are limited to one and a half times the width of the widest street on which they stand.

This is all there is of limitation by legal enactment of the height of buildings in this city, but, better late than never, the municipal authorities have recently interested themselves in a more general regulation of building heights, and have taken measures to secure expert advice as to what requirements would be satisfactory and practicable. Under Section 407 of the Charter of the Greater City of New York, the Board of Aldermen and the Board of Estimate are vested with power to limit heights, and it is to be hoped that before long a suitable method of restriction will be determined upon. In a statement made by the Fifth Avenue Association to the New York City Commission on the height, size, and arrangement of buildings, at a conference held this summer, it was mentioned that in the various cities in this country and Europe with height restrictions they have, with but very few exceptions, a maximum flat height limit either as the sole or the fundamental method. In some the so called “zone system” is employed, and this is the one favored by Mr. De Forest, president of the New York City Municipal Art Commission, who was the first head of the Tenement House Department in New York, in a letter he has written to the city commission referred to.

The Heights of Buildings Committee of the Board of Estimate and Apportionment, which is composed of the presidents of the boroughs of Manhattan, Brooklyn, and the Bronx, and its advisory committee, of which Mr. Edward M. Bassett is chairman, have invited the various medical societies of the city to send representatives to two general hearings on matters pertaining to the regulation of the height, size, and arrangement of buildings in the five boroughs of New York which are to be held respectively on October 10th and October 16th.

CHOLERA IN EUROPE.

That Asiatic cholera was again due in Europe was stated by many observers two years ago, and the Balkan war has added considerably to the progress of the disease. While it was admitted that the Turkish troops, mostly collected from Asia, suffered from a severe attack of cholera, the Christian allies were said to be in a better condition. For political reasons thorough statistics were not given out by these powers, but the records which now appear in the medical journals of Europe demonstrated how very severe the condition was. Servia, for example, had on its own frontier, three successive lines of inspection against cholera, a prophylaxis, which according to European medical observers, was splendidly carried out, as the quarantine might not have been carried out better if peace had reigned in the Balkans. But notwithstanding all the precautions, the threatened invasion of cholera has become a fact; not only has the disease gained a foothold on the Balkan itself, but it has crossed the Danube and reports come from its appearance in Rumania, in Hungary, and in Austria. At the same time Italy has its own troubles with the invasion from its new African possessions. There seems to be doubt whether the disease has really been stamped out in Italy, while the reports from Russia state that nine districts are severely infected. Thus it is plainly demonstrated that again cholera threatens to sweep over Europe.

TYPHOID FEVER IN NEW YORK CITY.

Through the daily newspapers and personal observations, we have come to the conclusion that there seems to be such an increase in cases of typhoid fever in certain quarters, that the decision may be reached that New York City is at present threatened with an epidemic of the disease. That the attack is well controlled by our Health Department goes without saying—for we have full confidence in the department, which has proved its value in many threatened epidemic attacks. Undoubtedly, those in authority are correct if they do not give out information which may lead to wrong conclusion, or result in an unnecessary public scare. But this is not the question. A thorough investigation should be made to discover the source of such an increase in typhoid fever cases. Usually infected milk supply or unclean water are given as the starting points in the daily press; or again the return of many people from unhealthy summer resorts. The quarters where at present the increase of the malady is reported is one of the most thickly populated of the city, where undoubtedly people live in unsanitary conditions. Not only the milk and water supply should be inspected, but as well
the meats and vegetables used. Whether this can be done we do not know, but it stands open to reason that with our present knowledge of typhoid fever, vegetables as well as meats can become dangerous carriers of the bacillus. As to meats we only have to watch the long incoming trains arriving at Hoboken or Jersey City, carrying carloads of chickens which reach the terminals in rather a poor condition. The conditions of transportation, the close packing, and the impossibility of giving water and food to the chickens result in many deaths before the poultry reaches the consumer and makes the fowls unfit for food, which then may, possibly, become a source of a dangerous epidemic.

STATE LAWS AND MARRIAGE.

The Eugenics Record Office has lately published its ninth bulletin, which contains a very interesting synopsis of the State laws limiting marriage selection examined in the light of eugenics. The pamphlet is written by Charles B. Davenport, of the Carnegie Institute of Washington, and deserves a wide circulation. It presents to the reader interested in this matter and especially in future legislation, the results of scientific investigation into some of the problems that have, first of all, a biological basis. An appendix contains the digest of State laws limiting marriage selection, up to April, 1913.

Obituary.

NATHAN JACOBSON, M.D.,
of Syracuse, New York.

Dr. Nathan Jacobson died in Syracuse, N. Y., on Tuesday, September 16. Born on June 26, 1857, in Syracuse, New York, he received his education entirely in his native town, graduating from the College of Medicine of the Syracuse University in 1877. After one year of postgraduate study in Vienna he returned to Syracuse, in which city he had practiced since, devoting himself largely to surgery. Since 1885, he had been connected with his alma mater as instructor and later as professor of clinical surgery. Interested in the medical societies, he held several offices in some of these associations. He was a valuable contributor to this Journal.

CHARLES LESTER LEONARD, M.D.,
of Philadelphia.

Dr. Charles L. Leonard died at Atlantic City, N. J., on Monday, September 22nd. He was born in 1861, and graduated from the University of Pennsylvania in 1889; he was later appointed professor of röntgenology at his alma mater. Doctor Leonard was an expert in x-ray work and another martyr to röntgenology. From constant exposure to the rays his hand became affected. The disease extended upward until the whole body was involved, notwithstanding the hand and later the entire arm were amputated. Doctor Leonard was a well known writer on röntgenology, and an esteemed contributor to our Journal.

Changes of Address.—Dr. James Moran, to 262 West Eighty-third Street, New York.
Dr. A. L. Benedict to 228 Summer Street, Buffalo, N. Y.

Southern Minnesota Medical Association.—Plans are being made for the midwinter meeting of the Southern Minnesota Medical Association, which will be held in Mankato on December 2d and 3d.

Meetings of Medical Societies to Be Held in Philadelphia during the Coming Week.—Wednesday, October 2d, Physicians' Motor Club, and the College of Physicians; Thursday, October 3d, Obstetrical Society; Friday, October 4d, Kensington Branch of the County Society and the Southeast Branch of the County Society.

Cholera in Rumania.—A report from Bucharest, dated August 28, 1913, stated that cholera had been increasing in Rumania. On August 26th there were present in Bucharest 212 cases of the disease. According to press despatches on September 2nd there were 1,137 cases of cholera under surveillance in the Rumanian capital. There have been forty-five deaths from the disease.

Smallpox in Oregon.—Acting Assistant Surgeon State, of the United States Public Health Service, reported on September 13th the occurrence of an epidemic of smallpox of a mild type at North Bend and Empire. Oregon, the disease having been present at these two places during the past two months. According to the September 16th issue of the Public Health Reports, the United States Public Health Service, 334 cases of the disease have been reported from April 1st to July 31, 1913.

Harvey Society Lectures.—The first lecture in the course for 1913-1914 will be given on Saturday evening, October 4th, at the New York Academy of Medicine by Augustus D. Waller, M.D., F.R.S., the distinguished physiologist of the University of London. His subject will be A Short Account of the Origin and Scope of Electrocardiography. Doctor Waller comes from London especially to give this lecture and brings with him apparatus with which he will give demonstrations during the lecture. He is a pioneer in animal electricity and was the first to record the human electrocardiogram. No one who is interested in this modern method of diagnosis of heart diseases should fail to hear Doctor Waller's lecture.

The Outbreak of Typhoid Fever in New York.—According to newspaper reports, the typhoid fever situation in the east side of New York is still serious. On Tuesday, September 23d, fourteen new cases were reported to the Department of Health, making a total of 225 cases in the hospital and many units in the city. While Bellevue Hospital is not filled to capacity, the wards are crowded, and both Israel Hospital, at 70 Jefferson Street, has been obliged to turn patients away on account of the crowded condition. The case rate reported to the east side of the city below Fortieth Street, as the cases reported in other parts of the city point to the fact that conditions are normal for this time of year. Investigations are being made by the Department of Health to ascertain the cause of the outbreak, but so far the results of these investigations have not been made public.

Personal.—Dr. John N. Bassin, of Poughkeepsie, N. Y., has been appointed assistant instructor in surgery at the New York Polyclinic Hospital and Medical School.
Dr. John S. W. Lock, of St. Louis, Mo., has been appointed dean of the medical faculty of St. Louis University, to succeed Dr. F. P. Lyon, who was recently appointed dean of the medical department of the University of Minnesota.

Dr. William Jepson, head of the department of surgery at the University of Iowa, has resigned.

Dr. P. Chaliss Bartlett, the retiring superintendent of the Rutland, Mass., State Sanatorium, was given a farewell banquet on the evening of September 16th by the members of the staff of the sanatorium. Dr. W. B. Howes, assistant physician, acting as toastmaster.

Dr. A. G. Pohlman, professor of anatomy in the Medical Department of the Indiana University, Bloomington, Ind., has been appointed head of the department of anatomy in St. Louis University.
Physicians of Essex County, N. Y., Organize.—At a meeting held in Port Henry, N. Y., on Monday evening, September 8th, the Essex County Medical Society was formed. Previous to this, Essex was one of three counties in the State of New York in which there was no medical society. Dr. S. J. Banker, of Port Edward, presi- dent of the board of the Medical Society of the State of New York, was organizer, and Dr. Abraham Jacob, of New York, read a paper. The follow- ing officers were elected to serve for the first year: President, Dr. E. B. Warner, of Port Henry; vice- president, Dr. C. B. Warner, of Port Henry; secretary, Dr. Charles Payne, of Westport; treasurer, Dr. W. T. Sherman, of Crown Point; censors, Dr. T. H. Canning, of Port Henry; Dr. W. F. Brown, of Mineville, and Dr. F. M. Noble, of Bloomingdale. The first regular meeting of the society will be held in Elizabethtown on the first Tuesday in June.

Mississippi Valley Medical Association.—The pro- visional programme has been issued for the thirty-ninth annual meeting of this association, which will be held in New Orleans on October 24th, 25th, and 26th, with head- quarters at the Grunewald Hotel, and preliminary arrange- ments for the reception and entertainment of the dele- gates have been made. Dr. W. W. Butterworth is general chairman of the committee. The names of other committees that are to assist in arrangements for the three day convention are: Dr. E. M. Hummel, finance, Dr. Allan Eustis, entertainment; Mrs. S. M. D. Clark, ladies' entertainment; Dr. J. F. Kelly, reception; Dr. C. E. Oechner, photographic exhibits; Dr. E. B. Martin, transportation; Dr. G. K. Pratt, Jr., chair- chairman; Dr. A. Nelken, registrations; Dr. C. N. Cha- vignon, badges; Dr. M. A. Shenker, hotels; Dr. William G. Sheehy, publicity; Dr. Oscar Dowling, sanitary exhibits; Dr. C. B. Young; Dr. J. T. D'Aquin, assistant chairman of the general committee. The officers of the association are: Dr. Albert E. Sterne, of Indian- apolis, president; Dr. D'Orsay Hecht, of Chicago, first vice- president; Dr. H. C. Cabot, of Boston, second vice- president; Dr. Henry E. Tuley, of Louisville, secretary; Dr. Samuel C. Stanton, of Chicago, treasurer.

American Public Health Association.—The annual meeting of this association was held in Colorado Springs. Colos. on Wednesday, Thursday, and Friday, September 9th, 10th, 11th, and 12th, under the presidency of Rudolph Herin, D. Sc., of New York. More than three hundred delegates were in attendance, almost every State in the Union being represented, as well as Canada, Mexico, and the West Indies. Numerous papers were read and discussed, many advanced ideas on matters relating to public health and sanitation being brought out, and it was the general opinion of the officials that the convention was the most successful of that nature. The names of officers resulted as follows: Dr. W. C. Woodward, of Washington, D. C., health officer of the District of Columbia, president; Professor Selskar M. Gunn, of the Massachusetts Institute of Technology, Boston, secretary (elected). Dr. John T. Gun, of New York, was elected president. The members of the executive committee are as follows: Dr. C. V. Chapin, of Providence, R. I., chairman; Dr. Noulau Cauchon, of Ot- tawa, Canada, vice-chairman; and re-elected Dr. E. C. Levy, of Richmond, Va., secretary, and Dr. A. S. Fell, of New York.
a lengthy, hard body, the point of which was felt externally. By light pressure with the external hand aided by the internal, the operator succeeded in removing the foreign body, which proved to be a goosequill ten cm. long. The product of conception, of five weeks growth, was removed, partly with the finger and finally by a curette. No antiseptic douching could be resorted to, on account of the perforation. Iodoform tampons were inserted, and an ice bag applied over the pelvis. The patient made a prompt recovery. When quizzed, she confessed that she inserted the goosequill herself with the hope of aborting pregnancy. On the following day upon lifting a pail of water she experienced a sharp pain, so severe as to cause her to cry out.

Rupture of the Uterus from Pituglandol.—G. Espent reports a case of ruptured uterus. The patient, thirty-four years old, had had seven spontaneous, full term deliveries. She was now at full term, and attended by a midwife. Pains began at eleven p. m.; membranes ruptured at one a. m.; later, the heart sounds ceased to be heard and the discharge of meconium caused the midwife to send for a physician. As none could be procured at the time, the patient was sent to a hospital. At 5:30 a. m. one dose of pituglandol, 1.1 c. c., was given subcutaneously to increase the pains. The cervix was widely dilated. Since, after one and one half hours, this did not, in the least, increase the pains, another dose was given; five minutes later the patient became restless and excited, as now very severe, quick pains ensued. The patient cried out suddenly; the pulse became feeble, and cold perspiration appeared on the forehead. Rupture of the uterus was diagnosed and laparotomy resorted to at once. The cervix was torn through on both sides, up into the parametrium. The uterus was extirpated. The child could not be resuscitated, and the mother died of general peritonitis on the third day.

Addison's Disease and Pregnancy.—E. Vogt states that Addison's disease is rarely complicated with pregnancy. Pregnancy may continue undisturbed. One case, a patient under the author's observation, resulted in stillbirth at full term. Another case was one of premature birth at the thirty-fifth week. Generally there is no cause for abortion. In the face of the bad prognosis for the mother, it is best to allow pregnancy to continue to full term, with the hope, at least, of saving the child. The prospects for the children are not bad, even when of premature birth. They develop normally.

The Danger of Combining General Narcosis with Morphine and with Narcotics.—W. Straub presents the history of a young person, who, on account of an accident, was to have a finger amputated. The child was given morphine with the idea of performing the amputation under its influence, which, however, was not feasible with the amount of pain experienced. For this reason chloroform was given, which proved fatal. The child died of paralysis of the respiratory tract. The depth of the narcosis was not abnormal and the dose of morphine was too small to be contested.

Seasickness and Atony of the Vagus.—Friedlander cites two forms of seasickness, the visceral and the nervous forms. A small proportion of the patients experience either only nausea and vomiting, or simply visceral discomfort. The second class of patients, along with these symptoms or without them, experience general depression with psychic, nervous symptoms. The author recommends several turns of a broad flannel bandage snugly applied to fix and elevate the stomach, the patient to retain the reclining posture. Atropine is recommended. The author considers this medication and mechanotherapy more promising than the administration of hypnotics or nerves.

Studies of the Secretion of the Pancreas and Stomach by Experiments on Dogs.—E. Schlagentweit and W. Stepp report their experiments on dogs, and conclude that the pancreatic secretion may be the result of various factors. The significance of each single factor is difficult to estimate. If the chemical excitation of hydrochloric acid is lessened we infer that an insufficiency of other regulations quickly results in severe injury to the function of the pancreas.

The Influence of Kuhlenkampf's Anesthesia on Neuralgia of the Brachial Plexus.—M. Thobben relates the history of a patient, who had been exposed to a draft while asleep. This supposedly resulted in severe pains above the clavicle, which radiated down the entire arm, which was very painful on pressure. Hot air baths, electricity, electric light baths, and antineuralgics were used, but all without result. Finally 20 c. c. of two per cent. novocaine solution were injected above the clavicle, after the method of Kuhlenkampf. The pain, as well as the tenderness on pressure, were at once relieved, also the swelling. Two weeks later the patient returned to his work. Two months later he was still entirely well and doing heavy work.

ZEITSCHRIFT FÜR UROLOGIE.

VOL. VII, NO. 1.

Primary Urethral Carcinoma of the Fossa Navicularis.—Ottow reports a rare case of this kind. Under local anesthesia he removed the penis at the penoscrotal junction; up to six months there was no return.

VOL. VII, NO. 2.

Urethral Calculus in Bilharziasis.—Pfeister had a case of bilharzia in which there was found an urethral stone which he removed through the urethroscope. He comments upon the frequency of urethral stone in bilharzia, stone occurring in seven per cent. of all cases.

VOL. VII, NO. 4.

Atrophy of the Prostate.—Posner has found that two opposite processes in the prostate, hypertrophy and atrophy may cause practically the same symptoms. In the only four cases of atrophy he has seen in the past three years the causes were, first, chronic gonorrhoea; second, senile involution; third, valves caused by atony of the bladder; fourth, questionable. Prostatectomy in these cases is more difficult than when the prostate is hypertrophied. The operation of election is the suprapubic.
Bladder Tumors in Aniline Dye Workers.—Lewin reports the case of a malignant bladder tumor in a man of forty-nine who six years before had left an aniline factory in which he had worked twenty-five years. This tumor when seen was not operable. The patient told of eight other cases occurring among the workmen in the factory; four apparently recovered without treatment; and four died, two after operation.

The Prognosis of Nephritis.—Strauss gives the comparison between the nitrogen content of the blood serum and that of the urine in normal cases, and also in cases of insufficiency of the kidneys. In the former there was from thirty to forty milligrammes of residual nitrogen in 100 c.c. of serum; while in the latter, when the kidneys became insufficient, the residual nitrogen was sometimes as high as 200 milligrammes. In cases which show high residual nitrogen in the blood prognosis is always grave. Death is always a matter of comparatively short time when more than 150 milligrammes of residual nitrogen was found in 100 c.c. of blood serum. But even a much lesser proportion by no means excludes impending uremia. The test is good in both acute and chronic nephritis.

Pain and Sleeplessness.—Robert Jones describes pain as "an uneasiness, varying from a feeling of slight discomfort to extreme distress; and it may arise from the derangement of any function; also from violence, pressure, or undue tension in any part of the body." Then, after a brief survey of the several general causes of pain in the broad sense indicated by the definition, Jones passes to the consideration of sleep, which he terms, "a biologic rest." The several suggested causes of sleep are related and support is lent to Durham's hypothesis which is to the effect that sleep is due to a diminution in the cerebral blood supply. Jones had a patient with a large tumor of the brain which projected through an opening in the skull and which was found to be distinctly smaller during sleep than when the patient was awake. Children under five years of age should have at least twelve hours of sleep a day, and from that age to fifteen years at least ten hours. In Jones's opinion much of the present increase in insanity in the young is due to the prolonged deficiency in the amount of sleep which is obtained. The remainder of Jones's paper deals with the measures to relieve pain and combat sleeplessness, and, after predating the removal of the cause where it can be found, proceeds to advocate almost everything from motor drives and baths through cathartics and purges to the use of morphine. Despite the multiplicity of the remedial measures discussed there is much in the paper which might be of occasional use to the practitioner, but the indications and limitations as laid down are so varied and complex that a perusal of the entire article is necessary for their understanding.

September 6, 1913.

The Value of Anociaassociation (Crile).—J. Henry Chaldecott and C. W. G. Bryan find nothing but praise for the methods of Crile, which they have now employed in some twelve cases which would otherwise have been most serious operative risks. They find its power of minimizing or totally abolishing postoperative symptoms most remarkable. In eleven abdominal cases one patient only was sick, and that very slightly. Two of the patients were women over eighty years of age, one having her gallbladder removed for carcinoma and impacted stones, the other her gallbladder opened and drained for acute cholecystitis. Neither of these patients had any postoperative symptoms, and they experienced so little discomfort that, until their wounds were dressed, they did not know that the operations had been performed. The authors do not find that the method lengthens the duration of operations, for, while it may take a little time to infiltrate with novocain, this is saved by the rapid induction of anesthesia. In their experience it has been possible in long operations to work with from eight to ten per cent. of oxygen, and if cyanosis occurs with this proportion it is usually found that the infiltration has been insufficient. Good relaxation has been obtained for the suture of the parieties, but here the use of gauze pads often seems to cause some rigidity which, however, disappears at once after their removal.

September, 1913.

Pituitary Extract in Obstetrical Practice.—B. P. Watson thus sums up his observations: Pituitary extracts have a powerful effect in inducing and in strengthening uterine contractions. The type of contractions induced is similar to that which occurs normally, although at first there may be a tendency to prolongation of the pains. Such prolonged contractions result in slowing of the fetal heart, but the child is seldom in danger. When given in the late part of the first and in the second stage of full time labor, the polarity of the uterine contractions is not interfered with, but in early abortions and early in the first stage a simultaneous spasm of the os may occur. Its chief field of usefulness is in the first and second stages of labor, when there is delay due to feebleness of the pains, alone or when combined with other complications, such as malpositions of the head, malpresentations, multiple pregnancy, slight narrowing of the pelvis, etc. In the induction of abortion, in the treatment of abortion already in progress, and in incomplete abortion, its action is so uncertain that it is not to be recommended, except in cases where the os is widely dilated. In the induction of premature labor its effects are uncertain, but if sufficient dose is given they may be good. In the induction of labor at full term and after, better results are obtained than in premature cases. It gives good results in many cases of post partum hemorrhage, but is not superior to the various preparations of ergot. It has the power of sensitizing the uterus, so as to allow these preparations to act more powerfully, the combination being most effective. It is a useful adjunct in the treatment of placenta prævia, used in conjunction with rupture of the membranes, the use of hydrostatic dilators, or turning.

Pain as a Symptom in Pulmonary Tuberculosis.—Robert C. Patterson says that although pulmonary tuberculosis is a comparatively painless disease, there occur a considerable variety of aches and
pains whose recognition and differentiation is important. We are apt to look on the majority of patients with this disease as neuroasthenic and to ascribe many of their complaints to this cause, but in doing so there is danger that an organic basis for their pains may be missed and treatment directed wrongly, or else neglected altogether.

Sterilized Pus for the Treatment of Infections and Sterilized Cancer Inoculations.—V. B. Nelson suggests using sterilized pus in the place of autogenous or other vaccines because of its great simplicity and cheapness; because the pus is truly autogenous, which is not true of vaccines prepared from organisms grown on artificial media, as the organism is changed by such growth; and because besides the bacteria pus contains toxines and antibodies, both extremely useful for therapeutic inoculation. His method of sterilizing the pus is to mix the pus, which must be evacuated as aseptically as possible, with an equal part of one in 40 solution of carbolic acid, in a small bottle. The mouth of the bottle should then be closed with a rubber membrane, and the bottle then put in a basin of cold water, which must be slowly brought to boil. To allow air to escape a hypodermic needle may be thrust through the rubber membrane. This heating should be repeated the next day. He begins with two minims as a dose, gradually increasing to fifteen. Inoculations are performed every other day.

Review on 422 Cataracts Done by “Smith’s Method.”—Ram Nath Trivedi performed this operation on seventy-two patients for immature cataract. Escape of vitreous took place during the operation in 5.92 per cent, and after the operation, in 3.31 per cent. from the patients squeezing their eyes. Rupture of the capsule took place in twenty cases, but in none of them was a secondary operation necessitated. Iritis occurred in only two cases and was of a mild type. Prolapse of the iris was seen in 1.5 per cent.; panophthalmitis in 1.4 per cent, largely to patients disturbing the dressings; delay in healing of wound very seldom; opacity of the vitreous, postoperative glaucoma, secondary hemorrhage, or detachment of the retina or choroid in no case. The average vision before discharge was 6/15 to 6/8; ninety-seven per cent got good vision for both distance and near; only 1.5 per cent. obtained poor vision from some pathological defect in the other refractive media. Glasses were prescribed at the end of three months. A table of twenty cases, that were seen again months or years later, showed that all had vision ranging from 6/8 to 6/5. These cases are said not to be selected, but taken simply as they came.

Gonococcus Vaccines and Glycerin Extracts of the Gonococcus in the Diagnosis of Gonorrheal Infections.—George Cheever Shattuck and W. Stewart describe their experiments which were undertaken with a hope of finding a reliable method of diagnosis for gonorrhea by means of a specific reaction. Three types of reaction have been observed after the subcutaneous injection of vaccine: The local at the point of injection; the focal at the seat of the lesion, and the general; but the concentrated vaccine used by the writers showed no superiority over that used by others for diagnostic tests. It produced in gonorrheal and in control cases a local lesion like that of a chemical irritant. They think that autolysis may have been a factor in producing the supposedly irritating properties of the vaccine; that the changes in it may have prevented it from producing a specific reaction; and that the unsatisfactory therapeutic effects of gonococcus vaccine may be traceable to autolysis. Glycerin extracts of the gonococcus inoculated by the method of von Pirquet caused, in a few cases, the formation of peculiar papules which may have represented a specific reaction. Most of the cases showed no definite reaction. Although their results were negative they believe that present knowledge justifies the hope that a valuable diagnostic test for gonorrheal infection may yet be devised through improved methods of preparing vaccines or extracts of the gonococcus.

The Pathological Lesion of Whooping Cough. F. B. Mallory says that although the bacillus discovered by Bordet and Gengou in 1900 has been generally accepted by bacteriologists as the cause of whooping cough, it has not been accepted to any extent by the profession because the organism has never been demonstrated in connection with any lesion, only in connection with the disease. In going over sections from an acute case of whooping cough he noticed what seemed to be minute organisms packed in large numbers between the cilia of the epithelial cells lining the trachea. Better sections and stains showed the organisms to be minute bacilli, present in great numbers over the surface of each cell. Similar organisms were found between the cilia of the cells lining the bronchi, also free in the bronchial secretion and enclosed in polymorphonuclear leukocytes, but never within the alveoli. The bronchopneumonia which so often complicates whooping cough, seems to be entirely due to other contaminating organisms. The action of the Bacillus pertussis seems to be largely mechanical. It interferes with the normal movements of the cilia and therefore furnishes a continual irritation which excites the coughing. The organism also secretes a mild toxine, as is shown in three ways: By a slight inflammatory exudation, by a lymphocytosis, and by the production of a specific antibody.

The Quality of Drugs Sold to Dispensing Physicians, by W. A. Puckner.—See this Journal for July 5th, p. 49.

Administration of Alkaloids before Anesthesia.—The conclusions of I. C. Herb are as follows: 1. The administration of morphine, scopalamine, and atropine before general anesthesia has certain advantages, but these are not sufficient to counterbalance the risks attendant on their employment. 2. The loss of the pupillary reflex is a serious handicap, as nothing else indicates so unerringly the degree of narcosis. 3. That the danger from ether, chloroform, or nitrous oxide is diminished is contrary to the evidence at hand. 4. They should not be employed when inexperienced anesthetists are in charge. 5. The routine use of certain fixed doses before every anesthetic, regardless of the patient's condition, should be discouraged. 6. The employment of alkaloids has a distinct field of usefulness before local anesthesia.

Vaccine Therapy for General Practitioners.—J. H. Richards believes that, as a rule, all chronic bacterial disease can be treated with advantage by means of vaccine, and also many acute diseases. The following bacteria have been advantageously employed in vaccine treatment: Staphylococcus, streptococcus, gonococcus, colon group (including typhoid), tuberculosis, pneumococcus, Pfeifer's and Friedlander's bacilli, and the bacilli of rhinoscleroma and acne. In regard to the dose, which is of utmost importance, he suggests the following rules: 1. The first dose, and this alone, is to be decided arbitrarily. 2. The second dose, and all succeeding ones, must be regulated by the effect of the first dose. 3. A marked local reaction at point of inoculation following the dose, and accompanied by increased severity in the symptoms of the disease, and slight or no improvement in patient's condition before time for next dose, indicates that too large a dose has been given. 4. Slight local reaction following the injection, and accompanied by slight or no improvement increased severity in the disease and followed by no improvement in patient's condition, indicates that the dose has been too small. 5. Slight or no local reaction, accompanied by moderate, slight, or no increase in the severity of the disease, and followed by improvement in patient's condition, indicates that a correct dose has been given. 6. The second dose after a correct dose has been given should not be administered until the negative phase has been well passed. This is usually within from two to four days.

The Administration of Salvarsan and Neosalvarsan by Enteroclysis. Report of Thirty-seven Injections.—L. Oulmann and J. L. Wolleim describe the technic employed by them, which involves a special apparatus, and state the conclusions derived from the literature and their personal studies as follows: 1. The administration of these drugs by enteroclysis has a place in therapeutics. 2. In general, this ought not to replace the intravenous method, because it is possible that, in passing through the intestinal mucous membrane or the liver after absorption, some of the salvarsan may be changed chemically, and in that way its therapeutic effect may be less to the unit of dose. 3. It should be used in children in preference to other methods. 4. It should be the method of choice when the intravenous method is not feasible. 5. The subject is worthy of further study, to determine the exact place of this method in the administration of salvarsan and neosalvarsan.

MEDICAL RECORD.

Clinical Studies on the Curative Action of Leucocyte Extracts in Infective Processes.—P. M. Niss, Jr., and J. G. Duver state that most workers have, in their search for biological therapeutic agents, directed their energies to the production of specific antisera, and have, with few exceptions, neglected to approach the question of the treatment of infections from the side of the intracellular resisting agents of the system. In many infections, however, the ultimate weapons of defense are the leucocytes, either in their normal state, acting as phagocytes, or possibly when breaking down in the circulation or in exudates. The paper is based on a series of erysipelas infections treated with leucocyte extract, comprising 138 cases, the great majority of which were of the most severe type. This was due to the fact that the authors were not consulted until the ordinary remedies had been tried; so that such cases probably offer as fair a test of the value of a therapeutic agent as could be devised. The majority of the infections were secondary to operative procedures, and the others were of the so called idiopathic form. The results obtained were so uniformly beneficial, constant, and marked that, judging from them, it would seem that in this disease we can almost prognosticate the results following the use of the extract. In every case there was a marked reaction following its employment, which was usually shown by a fall in temperature and rapid improvement in the general condition. The duration of an average case of erysipelas under the routine measures of treatment is about ten to fourteen days; while in this series of cases the average duration, whether treatment with the extract were instituted early or late, was 3.1 days after treatment had been begun.

Intestinal Hemorrhage in the Tuberculous.—J. M. Cruice says that while blood in small quantities in the stools of patients with pulmonary tuberculosis is not an uncommon occurrence, a hemorrhage of any size is rare. Guyenet divided the intestinal hemorrhages into the mechanical, or those due to rupture of a vessel in the site of an ulcer-
A Case of Varicose Ulcer Treated by Feeding It with Cheese.—G. O. Williams reports this case. Treatment was commenced May 1, 1913. The general treatment was by means of Blaude's pill. Local treatment: Soft well ripened full cream cheese, to which was added a mixture of equal parts of cream and water, was applied three times a day on a piece of gauze just large enough to cover the ulcer. The patient, a stout woman of fifty, doing farm, dairy, and household work, continued her regular occupations. The ulcer filled rapidly, and on May 20th was found to be fully healed; no scab even remaining. The author states that he has previously treated similar cases with soft, unsalted cheese curd with good results; but the progress has not been as rapid as in the present instance.

AMERICAN JOURNAL OF THE MEDICAL SCIENCES.

September, 1913.

A Lobar Form of Bronchopneumonia of Long Duration, Occurring in Children and Young Adults.—David Riesman gives the essential features of this affection as follows: 1. The disease is a confluent lobular pneumonia of lobar distribution characterized by long duration, low fever, and the following physical signs: Impairment of resonance, bronchovesicular breathing, and showers of crackling rales. 2. It must be looked upon as one of the causes of obscure long continued fever. 3. The disease always seems to end in complete recovery, both symptomatically and anatomically. 4. In the beginning, typhoid fever may be suspected; in the later stages, tuberculosis. 5. The disease is believed to be often overlooked, owing to the fact that the lower posterior aspect of the chest is seldom examined in ambulatory cases, especially when the symptoms are rather trivial. Seven cases are described in the paper, and the author states that in the treatment the measures which have appeared to be of some avail are counterirritation to the chest, abundant feeding, and either a simple cough mixture, with a small dose of an opiate, or one of the cresote preparations. In favorable weather he has advised that the patient should be taken outdoors, and a sojourn at the seashore in proper season is also beneficial.

The True Value of Operation for Cancer.—In order to estimate this, F. M. Foote says, we must know, 1, the object of the operation, and, 2, its result. Speaking broadly, there are four reasons for operation for cancer which may be present in the mind of patient or surgeon: 1. The complete removal of the cancer and cancer bearing tissue, the so called radical cure. 2. The establishment of a diagnosis. 3. The relief of some special symptom, such as hemorrhage, discharge from an ulcerating surface, the closure of a sinus, the division of a stiutre, or the removal of a disfigurement. 4. The attainment of certain social ends, to keep up the patient's hope or to satisfy the family that something is being done, etc. (Under this head should perhaps be admitted the possibility that the patient may die from operation, a hope which probably exists in the mind of the patient and his friends ofiener than they would like to admit.) In cases of advanced cancer one cannot hope to formulate specific rule to
cover the wide variety of conditions presented to the operator, but there are certain general principles which ought to be regarded: 1. The removal of the visible growth is desirable, so far as this can be accomplished without sacrificing important muscles, nerves, etc. 2. The wound should be so shaped that it can be entirely closed. 3. Lymph glands should be removed if they are readily accessible, even if deeper ones known to be involved are left behind. 4. It is of the utmost importance to save the patient's vitality by making the operation short, keeping the body warm, using a minimum of anesthetic, and, above everything else, keeping the loss of blood down to the smallest possible point. 5. If operation is performed for a special object, such as the relief of a plastic defect, it is generally wise to limit the operation to this, resisting the temptation to excise a few portions of the tumor because they are easily reached. 6. Plastic operations involving skin actually in contact with a cancerous growth may be successfully performed, and in the case of slowly growing tumors are often worth while. 7. Curettage or scraping an ulcerating cancer is of doubtful efficacy. In the second part of the paper the author presents the actual results observed from operations of the radical type, those for diagnosis, and those for special objects. In conclusion he urges that, while not every cancer patient with a recurrence should be operated upon, all patients who have been operated upon should be followed month by month, and single recurrences favorably situated should be promptly removed.

Therapeutic Artificial Pneumothorax.—H. M. King and C. W. Mills report that in sixteen cases in which this treatment was tried at the Loomis Sanatorium two patients have shown marked and apparently permanent improvement, six have shown temporary or slight improvement, in one, hemorrhages have apparently been controlled, in one case of lung abscess no improvement followed, and in six cases, on account of pleural adhesions, either no gas could be injected or not enough to produce any sufficient collapse.

The Diagnosis of Tuberculosis of the Kidney.—From a study of this subject F. E. Keene and J. L. Laird present the following conclusions: 1. The kidney is the primary seat of disease in tuberculosis of the female urinary tract; as a rule the infection originates from a focus in some other organ and gains entrance to the kidney by way of the blood stream. 2. The pathology varies greatly in both kind and degree. 3. Subjective symptoms referable to the kidney disease are by no means characteristic. 4. The most prominent symptoms are those referable to deranged bladder function, but these may be decidedly intermittent in their severity. 5. Some degree of pyuria is the rule; hematuria the exception. 6. In the absence of mixed infection the temperature is normal, or shows only a slight evening elevation. 7. The palpatory findings are dependent upon the type and extent of the pathological changes. 8. The tuberculin reaction is of doubtful value. 9. By far the most important agent in determining the diagnosis is the cystoscope, which in the majority of cases shows a picture so characteristic that the nature of the infection is at once recognized. 10. The diagnosis in every suspected case should be made by the combined clinical and laboratory examination. 11. The Bloch method of inoculation of guinea pigs should be used, and also the subcutaneous or intraperitoneal methods as controls. 12. A positive laboratory result by either method determines the diagnosis of tuberculosis of the genitourinary tract; of renal tuberculosis in the female, in the male the exact focus to be determined by additional clinical and laboratory means. 13. A single negative laboratory result, regardless of thoroughness of examination, does not determine an absolute negative diagnosis of renal tuberculosis, as the manifestation of this disease is essentially intermittent.

September, 1913.

Abderhalden's Test of Pregnancy.—Heaney and Davis describe in full detail the technic of making this test and give, as well, a résumé of some of the work done with this reaction. Their conclusions are as follows: A review of the literature and an experience with the test, together with the use of other means of testing the digestive activity of the blood, leads one to question the specificity of the test of Abderhalden; though, since the need of such a reaction is great the test should be further tried, and its results accurately reported.

The Treatment of Puerperal Infection.—Ingram reviews briefly the various methods by which autoinfection may arise; from a distant point of suppuration with metastasis through the blood stream; by extension from contiguous disease; and from the presence of pathological organisms in the vagina and vulva. On account of the presence of bacteria he considers that the risk involved by making frequent vaginal examinations is probably the greatest in the production of puerperal infection. The different ways in which infection from the outside may occur are mentioned and the treatment according to the locality and the extent of the infection is briefly summarized.

Tuberculosis of the Kidney.—Kapsammer, in an article of twenty-five pages, gives a very complete review of the subject. In going over his statistics he finds that tuberculosis of the kidney is, as a rule, unilateral, that men suffer with it more frequently than women, and that it is found on one side as frequently as on the other. In regard to the mode of infection, it seems that primary tuberculosis of the kidney, as a rule, is by the hematogenous route. From this organ it may extend to others of the urogenital structures along the ureter, by continuity of tissue, or else by the hematogenous or lymphogenous path. That an ascending infection of the kidney must be rare is shown by the experiences of several who found that an ascending infection could be brought about only by the ligature of the ureters when they are involved. After dealing with the morbid anatomy of the organ and the differential diagnosis, the therapeutic measures are discussed. The author believes that the operative therapy is the only rational treatment that can be considered at the present day. As soon as the diagnosis is made, a nephrectomy should be performed. Kapsammer advises the removal of
the kidney and the ureter, if diseased, in one piece so as to avoid, as much as possible, postoperative complications.

AMERICAN MEDICINE.
August, 1913.

The Pernicious Vomiting of Pregnancy.—R. A. Kingman is the author of this paper, and he gives the essential elements of the contention set forth in it as follows: 1. Pregnancy is a physiological process in which nausea and vomiting have no useful, necessary, or normal part. They are therefore never physiological, but always pathological, and therefore to be prevented or stopped in every case, and at once. 2. Toxemia plays no important part as a cause of pregnancy vomiting, though it is doubtless often present as a result of a common cause, and may be a factor in advanced cases. 3. Neurotic influences greatly increase susceptibility to reflex stimuli, as also the degree of the response; hence all such influences are to be sought out as important factors. 4. The essential, exciting, determining cause in all serious cases is a reflex disturbance proceeding from the uterus, usually from the cervix, and especially from the region of the internal os. 5. The important conclusion of the whole matter is that an intelligent treatment based upon this conception has resulted in quick, uniform, and permanent cure, in every case, during a period of twenty years, regardless of the stage or severity of the case; provided the patient was not moribund when first seen. 6. These results are not exceptional, but can be obtained by anyone who will fit himself to make an accurate diagnosis of the pelvic condition and to properly carry out the indicated treatment. 7. If prompt relief from suffering, and security from all danger, can be promised in every case, who will dare in future to counsel destruction of the child? In the vast majority of cases of pernicious vomiting in pregnancy there is present anteflexion of the cervix uteri, with varying descent of the uterus upon the pelvic floor and more or less fixation of the organ from thickening and contraction of the peritoneal cellular tissue. Kingman advises the employment of the knee chest position, which, he says, must be so used as to insure the free advance of all abdominal and pelvic contents toward the diaphragm, permitting the disposition of the vagina with air; and yet the patient must be so draped and protected as to avoid undue exposure, exertion, or fatigue. It is easy to-day to procure corsets which support the lower abdomen and remove all pressure from the waist and lower ribs. The useful but primitive cotton tampon and air ball of Graily Newitt are supplanted by an improved form of wood packing; though the Newitt air ball pessary may still serve a useful purpose in cases where, for any reason, the patient cannot be regularly seen and treated. The use of proper clothing and the intelligent treatment of anteflexion, with its attendant conditions, previous to the beginning of pregnancy, supplemented by proper advice, often succeed in making a patient immune to even the so-called "physiological vomiting."

Some Remarks on Arteriosclerosis.—I. L. Nascher holds that the fundamental error in dealing with arteriosclerosis is the almost universal conception of it as a pathological entity; whereas it should be recognized that there are many forms of arteriosclerosis, that this is a generic term covering several distinct pathological conditions, and that only in the terminal stages of these do they approach a general type and finally become a clinical and pathological entity. It will be found, he says, that of the various methods of treatment which have been advocated in arteriosclerosis, each is of service only in certain forms of it—that there is no one remedy, or no one method, applicable to all forms of the disease; while the simple, physiological form cannot be cured at all.

"Blue" Blood.—R. L. Watkins says that the color of the drop of fresh blood taken for examination is of important significance. Blood from the wrist or lobe of the ear, because it is capillary, is arterial, and thus normally red, while that taken from the end of the digits is blue, or venous, and thus always abnormal; since here the artery connects directly with the vein, without any intervening capillaries. Blood for examination should therefore be taken from the wrist or lobe of the ear, and if a drop of such blood is found of a dark blue color it is a sure indication of either excessive gases in the intestinal tract or stomach, or of decomposition or putrefactive processes going on somewhere in the system. If, on the other hand, the drop is crimson it is indicative of excessive oxygen in the corpuscles, or, possibly, too thin blood, as in leukemia and some cases of tuberculosis. The latter often alternates with the blue black condition, putrefactive products being present one day and absent the next, after being absorbed or thrown off. Blue blood is always present where there is intestinal indigestion with gases and decomposition of food.

ARCHIVES OF OPHTHALMOLOGY.
September, 1913.

The Experimental Production of Sclerokeratitis and Chronic Intraocular Tuberculosis.—F. H. Verhoeff, says that when dead tubercle bacilli are injected into the vitreous or the anterior chamber of a rabbit they produce, after about three months, lesions in the corneosclera closely analogous to those of tuberculous sclerokeratitis in man. Smaller tubercles are produced on and within the iris, and still smaller ones on and within the ciliary processes. The latter are of special significance, as they indicate that the foci in human cases of tuberculous cyclitis are not necessarily due to direct metastases from the blood. Tubercles of the choroid are also produced, due to bacilli passing from the filtration angle along the postchoroidal space. These observations confirm the theory previously advanced, that tuberculous scleritis and keratitis are due to infection from the aqueous through the filtration angle. They also strongly suggest that the chronic types of tuberculous iritis and cyclitis, and possibly choroiditis, are likewise due to metastases from the aqueous, the bacilli reaching the latter from the vessels of the ciliary body. The lack of immune substances in the aqueous no doubt increases the chances for such metastases to occur. In addition these observations suggest certain procedures in regard to treatment.
On the Treatment of Trachoma with Iodic Acid.—Josef Rudas gives the results obtained in the Military Hospital in Krakau, where this method of treatment has replaced all others since 1906. The iodic acid is moistened until it forms a plastic mass which is rolled into a rod. For comparison, 583 cases thus treated were compared with 553 cases treated by other methods. The average length of treatment was 44.12 days in the former, and 64.47 in the latter. Ulcer and panus occurred in 0.85 per cent. of the former, in 3.25 per cent. of the latter. Disturbances of vision were 0.51 per cent. in the former, 3.07 per cent. in the latter. Relapses occurred more rarely after treatment with iodic acid, with a difference of eight per cent. The eye is cocainized, the iodic acid rod is applied to the lower transition fold, which is then wiped dry with cotton and the superfluous iodic acid washed off with a three per cent. boric acid solution. Extreme care is not necessary, even if the noninfected parts of the conjunctiva are touched, as this acid does not attack the healthy cornea. The upper lid is then averted, and an application made in the same manner; the lid is then doubly everted with a forceps, and the upper transition fold cauterized in the same way. After cauterization the follicles should appear yellow, and if any are not of this color they should be cauterized again. The pain begins as soon as the effect of the cocaine wears off and varies in severity. A violent inflammation ensues, but after this passes off, the conjunctiva presents a clean wound surface. The formation of a symblepharon must be guarded against. The results are, in the first stage, complete recovery; in the moderately severe cases, a superficial, delicate, scarcely visible scar, which is much less than that following any other method of treatment; in the severe cases, better results than by other methods. Schiele asserts that good results are also obtained in the presence of ulcer and panus.

JOURNAL OF MEDICAL RESEARCH
August, 1912.

The Association of Tuberculosis and Malignant Growths.—Harris discusses the question whether the tuberculosis is primary and causes histological disturbances which provoke the formation of the neoplasm, or whether the earlier presence of the growth with degenerated areas form a vulnerable site for the Bacillus tuberculosis. It may, however, be possible that their association is merely a coincidence. After reviewing briefly the literature, Harris reports a case of tuberculosis of the larynx and cancer. In this instance it is his impression that the tuberculosis formed a primary pathological soil upon which the tumor probably thus provoked, continued to flourish, and the tuberculosis in part yielded.

NEW ORLEANS MEDICAL AND SURGICAL JOURNAL.
August, 1912.

Clinical Studies in Pituitary Irritation, with Report of a Case.—L. J. Genella reports a case which for a time presented the clinical picture of paresis, after which, preceded by persistent neuralgia, there occurred a gradual enlargement of the patient's right hand and foot, followed, within three months, by similar growth of the left hand and foot. There was no enlargement about the jaws. When the man died an autopsy was refused, but permission was received to trephine the skull, and it was found that there was no enlargement in the bony sella turcica. The author gives the main points of differentiation in the most common conditions which may be confounded with that met with in cases of this type, among which are Paget's disease, Charcot's disease, rheumatoid arthritis, osteitis deformans, gigantism, and myxedema.

Legislation—State and Local. What It May Accomplish for Sanitation.—S. D. Porter says that as yellow fever was banished from Cuba and plague from California, so may many of the diseases that are now causing thousands of deaths be eliminated by the passage of proper laws. Having referred to some of the measures requisite for the prevention of malaria, hookworm diseases, typhoid fever, and various other diseases, he states that no public health student can question the necessity for more adequate State and local legislation for the advancement of sanitation. Education of the people, however, must come before legislation, and this was very forcibly demonstrated in Louisiana during the yellow fever epidemic of 1905. Again, the educational campaign inaugurated in that State three years ago has been influential in bringing about increasing annual appropriations by the legislature for public health work. The author concludes with a few suggestions for State and local legislation which may accomplish more for sanitation: More liberal appropriations for public health work; the establishment of laboratories for the study of the causes of transmission of disease; laws prescribing the qualifications of health officers, establishing medical inspection of school children, establishing a chair of hygiene and sanitation in colleges and universities and more systematic teaching of these in all institutions of learning.

Further Observations of the Neutrophile Leucocytic Picture as a Guide for Tuberculosis.—W. J. Durell concludes that in the polynuclear neutrophile picture we have a means of determining when the toxic or harmful dose of tuberculin is about to be given or repeated; or when we are giving the supposedly safe smaller doses which are practically useless, i. e., when the bone marrow cells become prone to exaggerated function or to a dormant state or function. It is in the latter condition that the tuberculins are especially indicated, and can be used as a "whip in hand" in order to stimulate these cells into greater activity; thus favoring the supply of new cells, which soon become matured into more resistent cells, carrying in the blood circuit and to the diseased tissues the greatest amount of antibody substances, and raising the body's resistance to its efficient limit.

Ehrmann's Palmin Tests.—J. A. Storck reports that of eight instances in which he applied the test (described in the Berliner klinische Wochen-schrift, July 15, 1912), six proved positive, and in each the patient showed no evidence of any pancreatic disturbance. In the two instances in which no reaction occurred there were evidences of pancreatic disease, i. e., fat droplets, undigested meat.
fibres, meat nuclei in the feces, and sugar in the urine. Recently the author has been using palm oil free of fatty acids for testing pancreatic function, and finds it satisfactory.

NEW YORK STATE JOURNAL OF MEDICINE.
August, 1913.

Relief of Vesical Obstruction in Selected Cases.
—Henry G. Bugbee says that his method is applicable to certain types of obstruction of the vesical outlet due to stricture of the prostate urethra, contracture of the vesical neck, small enlargements of the prostate, prostatic nodules left after the perineal operation, irregular prostatic outgrowths, and certain tumors, where open operation is scarcely called for, often unsatisfactory in result, or is contraindicated on account of the condition of the patient. The treatment which he advocates is the destruction of the obstructing tissue by the high frequency current, applied in the manner originally proposed by Beer for the destruction of vesical papilloma. The current destroys any tissue which it penetrates; there is no bleeding, very little pain, the work is done under the eye, the extent of destruction can be limited, and there is no injury to structures which impairs the function of the organs. The bladder and urethral mucous membrane are anesthetized by filling the bladder with a solution containing four per cent. of novocaine dissolved in a one in 16,000 solution of epinephrin, leaving the fluid in the vesica for twenty-five minutes preceding treatment. The current is applied with a No. 5 copper wire through an indirect close vision No. 18 F. cystoscope. The terminal end of the wire for a quarter of an inch lies on the tissue to be destroyed and the current is turned on. The wire penetrates the tissue, bubbles rise from the surface, and after a few seconds of contact a gray furrow is left on the area to be destroyed. After a few applications bubbles may fill the field, which can be cleared by irrigation. Fourteen patients have been treated thus and all have shown improvement, there have been no unfavorable results, and there has been no tendency to recurrence of the trouble. In two cases of inoperable cancer the treatment gave great relief to the symptoms and considerably prolonged life.

The Medical versus the Surgical Treatment of Puerperal Eclampsia.—E. Gustav Zinke arrays a large number of statistics from various sources to show that all surgical intervention, no matter of what form, has accomplished little or nothing in reducing the mortality of puerperal convulsions. The collective statistics show that the maternal mortality under surgical intervention considerably exceeds thirty per cent., while with strictly medical care similar statistics show it to be only twelve per cent. Rest, chloral, and veratrum viride are the essential measures.

PENNSYLVANIA MEDICAL JOURNAL.
August, 1913.

Isolated Sclerotic Involvement of the Mitral Valve.—Robert N. Willson describes the condition as one of sclerotic thickening and deformity, causing insufficiency or stenosis, and often both. In the more advanced cases atheromatous degenera-

tion is often superposed on the sclerotic lesion, and in a large percentage of the cases there is a deposit of lime salts which has resulted in a greater or less degree of calcareous change. Of the etiology of the disease Willson is able to say little. It is certain that syphilis may be a causative factor, tuberculosis may be one, and it is possible that infection by other pathogenic bacteria may also be the underlying cause of a certain proportion of the cases. The physical signs, course of the disease, and particularly the auscultatory phenomena are often quite typical of the more common infective valvular lesions. But in many cases, regardless of age, there is a striking amount of arterial sclerosis. This has even been marked in a child of four years. Early arteriofibrosis, premature accentuation of the aortic second sound, and a tendency to left ventricular hypertrophy in the presence of signs of developing mitral disease give reason to anticipate fibrosis rather than the ordinary inflammatory lesion.

The Correction of Nasal Deformities.—George M. Marshall's operation is particularly suited to those cases of lateral deviation and depressions with obstructing deflections of the septum. An incision about one-quarter of a centimetre in length is made parallel with the normal line of the nose and over the nasal process of the superior maxilla on the side of the prominence. With a bevelled chisel with a width of about the length of the incision the nasal process of the superior maxilla is penetrated, the greatest caution being observed not to go beyond the bone through the mucous membrane. The opposite side is then treated similarly. Then by means of suitable forceps the fracture is completed on each side, completing the mobility of these bony processes. It may also be necessary to force the septum into correct position by the forceps if this is in malposition. It may be necessary to complete the straightening process by a sharp blow with the mallet over the prominent side of the nose. During the entire operation pressure must be maintained over the incisions when they are not the sites of work, this is to prevent hemorrhage and subsequent hematoma formation. The lines of incision are dressed with iodiformed gauze and collodion. In some cases nasal splints have to be inserted to maintain position. An important feature of the after-treatment consists in having the patient further the correct reposition by frequent pressure over the side of the nose which was prominent before the operation.

Proeceedings of Societies.

AMERICAN PROCTOLOGICAL SOCIETY.
Fifteenth Annual Meeting, Held at Minneapolis, Minn., June 16 and 17, 1913.

The President, Dr. Louis J. Hirschman, of Detroit, Mich., in the chair.

A Method of Operating on Fistula without Cutting Muscular Tissue.—Dr. Rollin H. Barnes, stated that this method was used in those cases of fistula which involved the sphincter mus-
An incision was made externally to the sphincter, similar to that made when incising an ischiorectal abscess. Through this opening the scar tissue was dissected out to the internal opening. An incision was then made at the skin margin, so that the middle of this incision passed through an imaginary longitudinal line drawn from the internal opening. A submucous dissection was then channeled out up to the internal opening. Gauze drainage was kept in this until the external wound was healed sufficiently. Then the submucous tract, which remained was incised under local anesthesia. No muscular tissue having been cut, the function of the sphincters was preserved intact.

Report of a Case of Fecal Tumor Associated with Hirschsprung's Disease.—Dr. Alois B. Graham reported a case of fecal tumor associated with Hirschsprung's disease, the clinical history of which was unique and exceedingly interesting.

A Further Consideration of Sir Charles Ball's Operation for Internal Hemorrhoids.—Dr. Alfred J. Zobel, after a trial of this operation, summed up his conclusions as to its value, as follows: That, as a modification of the old ligature operation, it was better than the latter, and at the same time was far superior to the clamp and cautery operation, in that it took care of and avoided the recurrence of that revoluted anal skin ring which generally became markedly edematous immediately after these operations, leaving behind skin tags after the swelling subsided. In every instance in which the essentials of Ball's technique had been followed out carefully the author's results had been exceedingly satisfactory. The operation was recommended.

Deductions Based on an Analysis of 3,000 Rectal Cases.—Dr. T. Chittenden Hill stated that the principal object of tabulating 3,000 consecutive rectal cases was to furnish data as to the relative frequency of the various affections of the rectum and colon. There was a total of 1,120 operations performed in this series, and some deductions of a practical nature were drawn from this experience. It was found that rectal ailments were more common among males than females, the ratio being three to two. Hemorrhoids formed a large proportion, forty-one per cent. of the total. Next in frequency were abscesses and fistulae, eighteen per cent., and the remaining disorders were tabulated as follows: Pruritus ani, eight per cent.; anal fissure, ten per cent.; colitis, six per cent.; prolapaps anus and procidentia recti, 3.7 per cent.; cancer of the rectum and sigmoid, two per cent.; benign growths, 1.5 per cent.; stricture, 1.5 per cent.; syphilis, two per cent.; constipation, 2.8 per cent. Other miscellaneous conditions were recorded which made up but a fraction of one per cent., such as anal verruca, congenital stenosis, patulous anus, furuncles, foreign body, incontinence, coccycodynia, trauma, sigmoid diverticulitis, etc.

Personal Reminiscences upon the Subject of Proctology.—Dr. J. M. Mathews told of his early experiences in his chosen field of endeavor. He related his meeting many years ago with those renowned surgeons who had made St. Mark's Hospital, of London, so famous. Having been called "the father of proctology," he gratefully accepted the title, and, like a father, he offered good advice to, and would ever cherish what he now termed his offspring, the American Proctological Society.

Z-Plastic Operation for Anal Stricture.—Dr. W. M. Beach stated that extensive cicatrizes, resulting from trauma, and involving the partial or entire anal circumference, not infrequently resisted the usual methods employed to restore the physiological function of the anus. He therefore employed what he termed a Z-plastic method when operating on an anal stricture. The principle underlying the procedure was the transposition of dermic tissue in such manner as to obliterate the crest of the fibrous band. The first incision was made along the crest of such a band; then incisions were made at right angles from both ends, but running in opposite directions, thus approximating the letter Z. The flaps thus outlined were dissected out, transposed, and sutured. Various modifications were permissible, according to the extent of the stricture.

Sphincteric Atrophy.—Dr. Ralph W. Jackson remarked that muscular atrophy about the anus produced more serious consequences than hypertrophy. The physiology of defection was studied, and the action of the internal sphincter and of the external sphincter and levators sharply contrasted with their different innervation. This was preparatory to consideration and classification of the causes of sphincteric disease and consequent degeneration. Congenital causes were found in imperforate anus and congenital anovaginal cloaca. Coincidental with general weakness cases occurred in infants, the aged, and the extremely ill. Traumatic causes were faults of proctological operations and after-care, or obstetric lacerations, or due to prolonged division by protruding piles or procidentia. Nerve causes were primarily sympathetic as in rectal stenosis, or central as in spinal cord lesions. Degeneration or absence of one sphincter without impairment of the other was considered. The unhappy consequences of sphincteric inadequacy were presented. Treatment was preventive or restorative. Neither availed much when due to nerve causes, except possibly in luetic cases. Of first importance was the minimizing of trauma, both obstetric and proctological (especially sphincteric incision). Repair of trauma should be immediate and accurate. Later attempts were much more difficult and uncertain on account of atrophic muscular changes, and often results must depend on cicatricial contraction and adaptation of other muscles, especially the levators, to sphincteric duty. Restoration of long overstretched muscles was largely dependent on general treatment. Sphincteric deficiency was a troublesome problem to every practitioner, and the prognosis was uncertain.

Further Observations on the Surgical Anatomy of the Large Bowel.—Dr. Granville S. Hames had a series of three x-ray pictures made on the same individual to show what actually happened when tubes were introduced into the bowel. The first showed a thirteen inch proctoscope introduced its entire length. The distal end was one inch above the umbilicus. The second showed an ordinary colon tube introduced its full length after the removal of the proctoscope. The tube passed along the sig-
moid up to the highest point (one inch above the umbilicus), and then turned upon itself, the distal end passing back into the rectum. The third radiograph showed the bowel injected with bismuth buttermilk, and the thirteen inch sigmoidoscope introduced again. This picture showed that it was impossible to pass any instrument high up in a normal colon, except by the greatest accident. The sigmoid was lifted up into the abdominal cavity; its lower arm was occupied by bismuth and the metal tube; while the upper segment of the sigmoid was seen very distinctly where it had dropped back from a point opposite the umbilicus into the pelvis to its junction with the lower extremity of the colon. He asserted the latter radiograph proved that it was impossible to pass a nonflexible instrument beyond the first half of the sigmoid. To control the outflow of fecal material in colostomies the author had found, in five cases operated in January of this year, that the hard rubber rod could be allowed to remain permanently, when used as in the Maydl operation. The opening in the intestine was above the rod. A thin gauze dressing was applied over the bowel, and a strip of gauze was thrown around the knuckle of the intestine, and overlying gauze was then tied under the supporting rod. The strip of gauze constricted both the upper and lower segments of the bowel, and exerted a most satisfactory control over these artificial openings.

The Anorectal Line: Its Clinical Significance. —Dr. Collier F. Martin, after discussing the development of the anus and rectum, stated that the anorectal line, or dentate border, had a very important clinical significance, in that it was the point at which both the blood supply and the nerve supply became differentiated. Above it the blood was carried by the portal circulation to the liver; while below it, the blood stream mingled with the general circulation by way of the inferior vena cava. Above it, the rectum was supplied only with visceral or sympathetic nerve fibres, while below it, the anus and its surrounding structures were supplied with spinal nerves, and by sympathetic filaments. These spinal nerves carried sensory impulses common to nerves having specialized cutaneous nerve endings. Below the anorectal line, as evidence of irritation of the spinal innervation, sensory disturbances were expressed in terms of pain, itching, formation, and in alterations in spinal sense of touch and temperature, with their modifications such as dryness and moisture. Stimuli producing these sensory disturbances showed their presence by exciting motor contraction, or by inducing alterations in secretion. Above the anorectal line all of the specialized spinal sensations were absent, only the visceral sensations being present. In the rectum it was only pressure and muscle sense that appealed to our consciousness. This sensation was translated in the brain into a desire for stool, which desire was inhibited or assisted voluntarily, as occasion might require. In general, there was a marked tendency for pathological processes to limit their invasion to the embryonic structure in which they began; the anorectal line being the "great divide" between the ectodermic and the endodermic structures. Rectal infection and malignancy rarely extended below the dentate border, while anal pathology usually remained below this line and the levator ani muscles.

Further Observations on Pruritus Ani: Its Probable Etiological Factor; Results of Treatment.—Dr. Dwight H. Murray, whose paper was a continuation of his investigations on the etiology and treatment of pruritus ani, gave some new points which he had observed during the past year, and his additional experience in the treatment of patients. He found no reason for materially modifying his former reports, but had gathered data which helped to prove the correctness of his previous work. He found streptococcic infection in three cases of pruritus ani and vulvae, and in four cases of pruritus that had involved the scrotum as well as the anus. These complicated cases improved, with the exception of two vulva cases, by the use of the vaccine treatment. During the past year Dr. Murray had increased his former series of thirty-two cases, by twenty-five additional cases, in five of which streptococcic infection was not found. These cases showed other infections, which still further proved the coccigenous nature of pruritus ani; and also demonstrated that other bacteria than streptococci might bear a causal relationship, as was hinted in his first paper on this subject. His cases, so far as he had been able to determine, had not been affected by diet. During the past year he had carefully investigated as to whether or not the itching extended into the anal canal beyond Hilton's white line, with the result that only in one instance did it extend beyond that point, and then only for a short distance. His investigations of the past year had given him additional proof that pruritus ani was not caused by any local lesion within the anal canal, and that when such lesions existed with pruritus ani they were coincidental. In the cases that had been operated in as for local lesions pruritus ani had not been permanently improved as a result of the operative procedure. His work showed that if a complicating infection existed, and other bacteria than streptococci were found to be the sole invading organisms, we must use the corresponding autogenous vaccine. The opsonic index, following a bacterial diagnosis, was the proper method for determining this. Dr. Murray gave statistics, in favor of his theory, drawn from three years original work on the subject; he also gave a summary of the results of treatment, showing the favorable clinical results with autogenous vaccines in a large majority of the cases treated. He summed up his conclusions, as follows: 1. Results of the past year's work continued to uphold the correctness of the bacterial theory of pruritus ani. 2. It was advisable to make a bacteriological examination of all cases of pruritus vulvae; also of cases of scrotal pruritus. 3. The coefficient of extinction of opsonins was a valuable aid in diagnosis in complicated and obstinate cases. 4. Pruritus ani in his series of cases rarely extended above the white line of Hilton, and it was still sub judice. 5. The presence of a skin infection with a local lesion gave an unfavorable prognosis for the cure of pruritus ani by an operative procedure. 6. The absence of a demonstrable skin infection and the presence of a local lesion, with pruritus ani, would justify us in making a favorable prognosis for the cure of the pruritus ani by an operative procedure. 7. Prurit—
tus ani, with such infection as had been demonstrated, and a lesion existing in the anus or rectum, according to his statistics, was a coincidence; and the latter lesion was not the cause of the pruritus ani. 8. The sphincter muscle did not allow a leakage of rectal mucus upon the anal skin of one who had pruritus ani, except there was a patulous anus, any more than it did in a normal individual who had no pruritus ani. The moisture of the parts was due to a low grade inflammation of the infected anal skin.

Treatment of Fistula in Ano.—Dr. J. A. MacMillan gave three essentials for the operation for this condition: 1. An incision that would open up every ramification of the fistulous tract. 2. The excision of the fibrous tissue which formed its walls. 3. Free drainage, and a regulation of the granulation by means of pressure by gauze packing.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting Held May 28, 1913.

The President, Dr. CHARLES A. E. CODMAN, in the Chair.

Dr. WILLIAM L. CLARK showed a case of epithelioma of the lip in a man, sixty-five years of age, which had been treated by desiccation, with no return of the growth in seventeen months.

The Gonococcus Complement Fixation Test and Analysis of Results from Its Use.—Dr. B. A. THOMAS and Dr. ROBERT H. IVY were the authors of this paper, which was read by Doctor Thomas: In recognition of the admirable work by Schwartz and McNell on the complement fixation test in gonococcic infections, the fact must not be overlooked that Miller and Oppenheim in 1906 were the first to apply this reaction to a gonorrhceal affection and consequently were entitled to the distinction of being termed the originators. The present popularity of this test had been the outgrowth of the suggestion imposed by Schwartz and McNell, namely, the employment of a polyvalent antigen. Careful analysis of the gonococcus complement fixation test performed with the sera of the cases tabulated in their series would seem to justify the following assertions: 1. A positive reaction was invariably trustworthy and always denoted the presence of a focus of gonococcic infection. 2. A negative reaction frequently failed to determine the presence of disease, especially in the acute and subacute stages, when limited to the urethra and never if confined to the anterior urethra or vagina alone. 3. In no alien nongonorrhceal infections or systemic disease had a positive reaction been obtained, the test, therefore, appearing absolutely specific. 4. A positive reaction had been found to be present in 21.05 per cent. of patients clinically cured. 5. Not infrequently positive reactions would be discovered in patients denying gonorrhoea, either when suspicious lesions were presented or accidentally. 6. In only 9.00 per cent. of cases of acute and subacute anteroposterior urethritis had the complement fixation test resulted positively. The earliest appearance of a positive reaction in a primary attack of posterior urethritis, without complication, occurred in the sixth week. 7. In a number of cases of chronic recurrent urethritis, with acute exacerbations, the test was invariably positive; many of these patients undoubtedly had prostatitis. 8. The reaction resulted positively in one third of all cases of chronic posterior urethritis; undoubtedly many of these patients had a mild or low grade prostatitis. 9. In 52.08 per cent. of cases of chronic prostatitis a positive reaction was obtainable. 10. Two thirds of all stricture cases demonstrated a positive test. 11. In epididymitis, a positive complement fixation test was observed in 87.5 per cent. of cases. If from this series one case, probably tuberculosis, might be eliminated, and a time duration of five weeks could be imposed, the positive results in this form of disease had been 100 per cent. 12. In arthritis, undoubtedly gonorrhceal in character, positive reactions were obtained in 100 per cent. of cases. 13. In the diagnosis and differential diagnosis of pelvic disease in women, the gonococcus fixation test was destined, unquestionably, to play an important rôle. The authors had been unable to obtain positive results in uncomplicated urethritis, vulvovaginitis, and Bartholinitis, and it would appear that the infection must ascend at least to the level of the uterus in order to produce a positive blood response. 14. Inoculations of gonococcus bacterin, antigonococcic serum, and gonorrhceal phylacogen, might in themselves, by the production of immune bodies, be causes of positive reactions. How long these immunizing effects might endure was unknown, but they had observed patients, treated by immunotherapy, who one year later demonstrated negative complement fixation reactions. 15. Although the bacteriological demonstration of the gonococcus culturally was the only absolute method for its identification in chronic inflammatory processes, the method as a routine procedure was impractical and susceptible of many failures and fallacious results, so that the complement fixation test was not only less laborious, but productive of a higher percentage of positive findings.

Some Remarks on the Proposed Legislation in Regard to the Feebleminded in the State of Pennsylvania.—Dr. J. NORMAN HENRY called attention to the enormous expense entailed on the State in the support of those who for mental causes, many of which were hereditary, were unable to support themselves. The proposed legislation to confine feebleminded women to institutions during their childbearing life was a good plan, but inadequate to meet the necessities. Men also should be restrained either physically or physiologically. Under ideal conditions of prevention of procreation of the feebleminded, the eighty per cent. of such people, who were estimated to suffer from their vitiated inheritance, might be done away with and a new impetus given to the study and cure of the remaining twenty per cent. who were apparently without hereditary taint.
State Control of Medical Practice. Its Possibilities and Its Limitations.—Dr. Max Goeppe gave a brief historical review of legislation bearing on medical matters during colonial times, and quoted laws in force at the present time in Pennsylvania and the several acts preceding it during the last thirty years. The duties and powers of the Bureau of Medical Education and Licensure were to influence the general standard of practitioners through control of preliminary education; to influence and gradually improve the standard of technical efficiency through control of medical education and examinations for licensure; to revoke license to practice on proof of moral turpitude or habitual inebriety; and to exercise some control over special systems of practice by prosecution of persons not legally qualified to practise. He spoke of the impossibility of completely eradicating quackery. Regulation of the financial status of medical practitioners was desirable, but not feasible by legal means. The remainder of the paper was devoted principally to methods of State board examinations and the discussion of questions asked.

Acute Phlegmonous Cholecystitis; Report of a Case with Gangrenous Enteritis.—Dr. Albert E. Roussel observed that the extreme rarity of the conditions mentioned in the title, either alone, and more especially combined, prompted the recital of the facts of the case as he knew them and the detailed findings at necropsy. Perusal of the literature revealed no absolutely similar cases. In the case here recorded there was sudden onset with symptoms of myocarditis, purpura hemorrhagica, and gastritis with a very rapid course terminating within a few hours in death. No other case quoted in the paper showed evidence of myocarditis, although in Eskridge’s first case pericarditis and endocarditis were present, and in Salter’s case endocarditis and symptoms of heart trouble were observed. Babcock showed a relationship between chronic cholecystitis and myocardial disease, mentioning a definite case in his own experience, but his case was not of a phlegmonous or gangrenous character. The purpuric spots mentioned in the case in this paper were not observed in any of the other cases. The autopsy findings were, briefly, emaciation, edema, purpuric spots, ulceration of the lobes of the ears and tip of the nose, extensive gangrene of small intestine, extensive discoloration of the stomach and colon, cholecystitis with ulcerated areas, gray necrotic membrane, and one gallstone, few areas of fat necrosis in the pancreas, cloudy swelling of the kidneys, pericardial effusion, healed nodule of tuberculosis in the right pleura, congestion of both lungs, active tuberculosis of the right lung, and ulceration of the stomach. In view of the extensive inflammation of the entire gastrointestinal tract beginning with gastritis and gastric ulcer, passing into gangrene in the small intestine, and terminating in inflammation and discoloration in the colon, it was reasonable to presume that it was due to streptococcal infection that extended into the gallbladder producing similar changes in that structure. It may be presumed that a mixed infection in the tuberculous right lung of the patient, aided by the crippled heart, permitted a generalized streptococcal infection of the gastrointestinal tract. It must be concluded that gangrenous cholecystitis might occur independently of impacted gallstones or typhoid fever and might be secondary to a similar process in the intestinal tract. Also it must be admitted that gangrenous enteritis independent of obstruction, intussusception, or malignant disease might occur as the result of some virulent infection, probably streptococcic, and might extend into the gallbladder by continuity of structure. Further such infection might gain access to the gastrointestinal tract directly or indirectly from localized foci. That the several organs of the chest and abdomen must be below par for the culmination of this process must be acknowledged, since all of the cases enumerated showed more pronounced changes in the gallbladder and intestines, the more disturbed were the other viscera. In the face of these facts the conditions must be regarded as a fatal disease.

Letters to the Editor.

CEREBROSPINAL Meningitis.

173 Lexington Avenue,
New York, September 14, 1913.

To the Editor:—In yesterday’s issue of your esteemed Journal I noticed Dr. M. C. Ogan’s paper, Cerebrospinal Meningitis—References to Some Recent Literature. Will you kindly permit me to call the author’s attention to his omission to mention my numerous papers on the continuous warm water bath treatment of this disease, the most recent of which being included in my article, The Continuous Warm Water Bath, the Rational Remedy in Tuberculosis (Phthisiatisis) and Infectious Diseases in General, published in the International Clinics, June, 1913.

A. Rose, M.D.

Book Reviews.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

This third edition fully maintains the excellent standards of its predecessors. Although the second edition came out but a year ago, there is much that is new and important that has been added since then. Abderhalden’s serodiagnosis of pregnancy is given in much detail, and the older reactions, such as the Wassermann, are very clearly presented. The book is a very useful one and should be had by all who are doing clinical laboratory work.

Burdett’s Hospitals and Charities for 1913. Being the Year Book of Philanthropy and the Hospital Annual. Containing a Review of the Position and Requirements, and Chapters on the Management, Revenue, and Cost of the Charities. An Exhaustive Record of Hospital Work for the Year. A Useful and Reliable Guide to British, American, and Colonial Hospitals and Asylums, Medical Schools, and Colleges, Nursing and Convalescent Institutions, Consumption Sanatoria, Religious and Benevolent Institutions and Dispensaries. By Sir Henry...

The twenty-fourth publication of Burdett's Hospital and Charities is, as usual, a very complete handbook without which no hospital or charity association or editorial office can exist. Compared with the previous issues there is hardly any change made in the general makeup.

In this volume of the Students Aids Series the publishers have produced a very good book of its kind. One that would be quite useful in reviewing rapidly the more prominent points. It cannot, however, on account of its small size, give the subject of gynecology the consideration that it should receive.

Meetings of Local Medical Societies.

WEDNESDAY, October 1st.—Brooklyn Society for Neurological Society of Alumni of Bellevue Hospital; Harlem Medical Association, New York; Bronx Medical Association; Elmhurst Academy of Medicine; Schenectady Academy of Medicine.

THURSDAY, October 2d.—New York Academy of Medicine (stated meeting); Brooklyn Surgical Society; Danville Medical Association; Practitioners' Club of Buffalo; Geneva Medical Society.

FRIDAY, October 3d.—New York Academy of Medicine (Section in Surgery); New York Microscopical Society; Gynecological Society, Brooklyn; Manhattan Dispensary Medical Society; Practitioners' Society of New York; Corning Medical Association; Saratoga Springs Medical Society.

Official News.

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the fourteen days ending September 17, 1913:

Preble, Paul, Passed Assistant Surgeon. Upon the completion of duty in connection with the pollution of boundary waters between the United States and Canada, directed to return to station at Washington, D. C.; granted leave of absence for five days' leave of absence from September 6, 1913. Ramus, Carl, Surgeon. Granted fourteen days' leave of absence from September 17, 1913. Reichard, M., Acting Assistant Surgeon. Granted seven days' leave of absence from August 15, 1913, under paragraph 564, Service Regulations. Rammel, George, Assistant Surgeon. Granted twenty-one days' leave of absence from September 8, 1913, de Valin, Hugh, Passed Assistant Surgeon. Directed to proceed to Cumberland, Md., and vicinity for the purpose of cooperating with the State and local health authorities in investigations of the typhoid fever situation. White, J. H., Surgeon. Directed to represent the Service at the annual meeting of the Mississippi Valley Medical Association, at New Orleans, La., October 21 to 23, 1913. Wilson, R. L., Passed Assistant Surgeon. Granted seven days' leave of absence from September 6, 1913.

Board Convened.

Board of medical officers convened at meet at call of the chairman in New York City for the preparation of a manual for the mental examination of immigrants. Detail for the board: Passed Assistant Surgeon T. W. Salmon, chairman; Passed Assistant Surgeon E. H. Mullan; Assistant Surgeon George Parcer; Assistant Surgeon H. A. Knox; Assistant Surgeon G. A. Kempf; and Acting Assistant Surgeon B. Glueck.

United States Army Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Army for the week ending September 20, 1913:

Bradley, Alfred E., Lieutenant Colonel, Medical Corps. Ordered to Watervliet Arsenal to investigate with supply, etc.; Burnett, Thomas W., First Lieutenant, Medical Corps. Now on temporary duty at Fort Rosecrans, Cal., is assigned to permanent duty at that post in addition to his other duties; relieved from further duty at Fort Casey, Wash. Wade, W. T., First Lieutenant, Medical Corps. Ordered to Fort Riley, Kan., extended fifteen days. Chamberlain, W. P., Major, Medical Corps. Left Plattsburg Barracks on September 16th on twenty-one days' leave of absence. Crabtree, George H., Major, Medical Corps. Relieved from duty with the Philippine Islands, or the Isthmus of Panama and will proceed to Camp Douglas, Ariz., for duty. Crum, Wayne H., Captain, Medical Corps. Upon arrival in the United States will proceed to Fort Des Moines, Ia., from Fort Snelling, Minn. Draper, W. H., Second Lieutenant, Medical Corps. Grant leave of absence for seven days. Drake, Percy G., First Lieutenant, Medical Reserve Corps. Relieved from duty at Fort McKinley, Me., and will proceed to the Philippine Islands on December 5, 1913. Faissi, J. Vincent, First Lieutenant,
Medical Reserve Corps. Ordered to active duty from September 17 to 27, 1913, and will report at Fort Logan, Colo., for duty. Replacements for Captain Hoyt, Fort Hood, Texas, and Lieu-
tenant, Medical Corps. Joined Camp E. S. Otis, Canal Zone, on September 8, 1913. Henry, Ziba, First Lieu-
tenant, Medical Reserve Corps. Relieved from duty at Fort Sill, Okla., and will proceed to the Philippine Islands on December 5, 1913. Hereford, John R., First Lieu-
tenant, Medical Reserve Corps. Relieved from duty in the Philippine Department, effective on January 15, 1914, and will proceed to the United States. Hull, Howard L., First Lieutenant. Granted leave of absence to report to the Department of the Philippines, in accordance with the order of the Surgeon General. Kershaw, John F., First Lieu-
tenant, Medical Reserve Corps. Ordered to report to the Army Medical School on September 26th for required course of instruction. Kinsey, Oliver, Jr., First Lieu-
tenant, Medical Reserve Corps. Relieved from duty at Fort Washington, Md., to take effect September 30, 1913, and will then proceed to his home and on arrival will report to the adjutant general of the army; granted leave of absence from October 1 to and including November 23, 1913. Micke, Henry C., First Lieutenant, Medi-
cal Corps. Granted leave of absence for twenty-four days, effective on his being relieved from treatment at the Walter Reed General Hospital. Miltenberger, Val E., First Lieutenant, Medical Reserve Corps. Granted leave of absence for one month. Mitchell, L., First Lieutenant, Medical Corps. Reported for duty at Fort Lawton, Wash. Moncrief, William H., Captain, Medical Corps. Relieved from duty as attending surgeon, Fort Independence, Camp Funston, Kansas, and ordered to the United States. Munson, E. L., Major, Medical Corps. Leave of absence extended to January 15, 1914, for duty at Camp Travis, San Antonio, Tex. Left Fort Preble, Maine, to proceed from Maine to New York, and will proceed to New York, aged seventy-five years. Peter,—In Baltimore, Md., on Saturday, September 14th, aged sixty-eight years. Dunke.—In Rochester, N. Y., on Thursday, September 11th, aged sixty-eight years. Dunkel.—In London, England, on Friday, September 27th, Dr. W. S. Forbes, aged eighty-four years. Smith.—In Cambridge, Mass., on Wednesday, September 25th, Dr. W. E. A. Smith, aged eighty-two years. O'Neal.—In Mechanicsburg, Pa., on Thursday, September 18th, Dr. Lindsay P. O'Neal, aged seventy-five years. Raessler.—In Sioux City, Iowa, on Sunday, September 15th, Dr. Robert S. Wallace, aged forty-five years. Ross.—In London, England, on Friday, September 27th, Dr. F. W. Forbes, aged eighty-four years. Smith.—In Houston, Texas, on Wednesday, September 11th, Dr. W. L. Smith, aged thirty-five years. Wallace.—In New York, aged eighty-two years. Wenner.—In Wilkes-Barre, Pa., on Monday, September 16th, Dr. Alfred J. Wenner, aged forty-nine years.

BIRTHS, MARRIAGES, AND DEATHS.

[New York Medical Journal]

FROM THE MEDICAL CORPS OF THE UNITED STATES NAVY.

BIRTHS, MARRIAGES, AND DEATHS.

BIRTHS.

Kneestep.—In Hampden, Va., on Friday, September 5th, to Dr. and Mrs. William E. Kneestep, Jr., a son.

MARRIAGES.

Brophy.—School.—In Philadelphia, on Wednesday, September 17th, Dr. and Mrs. Arthur J. Brophy, of Miss Carolyn H. School.—In Washington, D. C., for duty. Munson.—First.—In New York, aged seventy-five years. Wilde.—In Baltimore, Md., on Saturday, September 14th, aged sixty-eight years. Currie.—In Chatham, Mass., on Saturday, September 20th, Dr. John Green Currie, of New York, aged thirty-four years. Case.—In Warrens-
burg, Mo., on Sunday, September 14th, Dr. Zophar Case. Curtis.—In Buffalo, N. Y., on Thursday, September 11th, Dr. Samuel C. Dunkle, of Glenwood, Iowa. Herman.—In Baltimore, Md., on Saturday, September 13th, Dr. Nathan Herman, aged fifty years. Jacobson.—In Syracuse, N. Y., on Tuesday, September 17th, Dr. Albert F. Jacobson, aged fifty-six years. Moore.—In Saranac Lake, N. Y., on Saturday, September 13th, Dr. Robert Emery Moore, of Brooklyn, aged thirty-four years. Norwood.—In Spencer, Mass., on Thursday, September 11th, Dr. H. L. Norwood, of Norwich, Conn., aged forty-three years. O'Neal.—In Mechanicsburg, Pa., on Thursday, September 18th, Dr. Lindsay P. O'Neal, aged seventy-five years. Raessler.—In Sioux City, Iowa, on Sunday, September 15th, Dr. Robert S. Wallace, aged forty-five years. Ross.—In London, England, on Friday, September 27th, Dr. F. W. Forbes, aged eighty-four years. Smith.—In Houston, Texas, on Wednesday, September 11th, Dr. W. L. Smith, aged thirty-five years. Wallace.—In New York, aged eighty-two years. Wenner.—In Wilkes-Barre, Pa., on Monday, September 16th, Dr. Alfred J. Wenner, aged forty-nine years.

DEATHS.

Original Communications.

ULTIMATE RESULTS OF THE CHETWOOD OPERATION FOR RETENTION OF URINE.

By E. L. KEYES, JR., M. D.,
New York.

Not so many years ago very few surgeons realized that such a condition as contracture of the neck of the bladder really existed, or that there were types of prostatic retention (including prostatism without hypertrophy, and prostatism due to relatively small, fibrous, concentric hypertrophy) for the treatment of which the usual methods of prostatectomy were not thoroughly satisfactory. But the discussion of the operations of Chetwood, Young, and Goldschmidt before the American Medical Association last year proves that many men now recognize and are prepared to combat these conditions. Therefore it is no longer necessary to apologize for attacking the prostatic bar and allied conditions by means of electric cauterization.

During the past ten years I have employed the Chetwood operation upon about one quarter of my cases of prostatic hypertrophy. I have also employed it for the removal of all minor obstructions, such as bars and contractures at the bladder neck, when simple perineal section seemed likely to prove inadequate to afford proper drainage for the bladder. In selecting cases for such an operation one is likely to err on the one hand in operating upon patients with little or no retention, but suffering from painful and frequent urination, and who would do as well without operation upon the bladder neck; or, on the other hand, in attempting to relieve by cauterization an obstacle requiring prostatectomy. The former error I have fallen into once, in the case of a patient without residuum who had suffered for a long time from painful and frequent urination, the cause of which I was unable to ascertain. I did a perineal section, burned what appeared to be a bar at the bladder neck, and although the operation did the patient no harm, it certainly did him no good. He was killed five years afterward in an accident, and up to the time of his death he had much the same pains as when he first consulted me. The other error, viz., that of operation upon prostatics who would do better by prostatectomy, is rather hard to estimate. I find that my results from operations upon lateral or bilateral hypertrophies (elevating a bar at the neck of the bladder) and upon small general hypertrophies, average about as well as those from operations for contracture, though I am more and more inclined to submit definite cases of hypertrophy to suprapubic prostatectomy.

In many instances, however, the motive for electing this operation has been the patient’s bad general condition. For the Chetwood operation causes less shock than any form of prostatectomy. It may be performed under local anesthesia, or in two stages, or if the whole operation is performed at once, it takes but five or ten minutes. The hemorrhage is insignificant; the convalescence less stormy than that of prostatectomy. I cannot compare the Chetwood operation fairly with the procedures of Young and Goldschmidt, for I have never employed either of these, being unwilling to trust to the precise accuracy of my urethroscope or cystoscope in diagnosing the shape and size of the prostatic obstacle, for experience has shown me that this sometimes differs materially from what the examination had led me to expect. A very amusing instance of this occurred last Spring when I cystoscoped a patient and demonstrated a projection of the right lobe. I then performed perineal section, and found the urethra pushed sharply to the right by an adenoma, about the size of a marble, in the left lobe. Yet, this projecting mass was almost entirely within the urethra and the very slight and unimportant enlargement of the right lobe was all that had been seen at the bladder neck. This patient was relieved of his retention by cauterization of the bar, and excision of the adenoma from the left lobe of the prostate, from within the urethra. Indeed, an evident advantage of operating through a perineal incision is that one can deal with any and all urethral conditions found, be they stricture, prostatic abscess, or actual obstruction at the bladder neck; and at the close of the operation palpation verifies the result. Moreover, the presence of visibly or palpably enlarged lateral prostatic lobes in no way interferes with the success of the operation, as it does with the clip operation of Young. I have, as in the case just cited, once or twice removed whole lobes, and have several times made two incisions in the prostatic bar, and pulled out a small piece of tissue between. Thus, the operation has a distinctly wider scope than that of the intraurethral operations. Moreover, its field is one on which prostatectomy scarcely encroaches, for the smaller types of prostatic hypertrophy are confessedly the most troublesome to deal with by prostatectomy.

Let us now turn to a consideration of results. Beginning with two operations in 1901, I have per-
formed fifty-seven Chetwood operations with two deaths, both due to sepsis; one on the thirteenth day and one at the end of the fourth week. A third patient was operated upon for complete prostatic retention. He left the hospital in three weeks, healed, emptying his bladder and in satisfactory general condition. Three weeks after this he died, his death being apparently due to chronic colitis. He had no further urinary symptoms, and I do not believe that the operation hastened his demise. Of the remaining cases some failed to be cured for two reasons, either the prostatic obstacle was not sufficiently removed (in which case the patient continued to have residual urine, and after a lapse of time the symptoms returned, or increased); or, the obstacle was too fully removed (leaving the patient with incontinence of urine).

INCOMPLETE RELIEF.

Eliminating from our statistics one case of tuberculosis, four cases of tubercle, and three of carcinoma, the patients surviving operation and whose ultimate results at present do not concern us, incomplete relief was afforded to seven patients.

The very first patient I operated upon was seventy-one years of age, and had chronic complete retention from a contracted bladder neck, stone, relapsing epididymitis, and acute renal infection. His bladder neck was burned, his stone removed, his right vas deferens tied off. The suppuration in the right testicle nevertheless continued, and required incision during the convalescence. He returned home six weeks after operation with a residuum of from three to five ounces. In the three months following operation he gained thirty-five pounds, but continued to pass water every hour or two by day, and from two to four times at night. Eighteen months after the operation he began to lose ground again and died of his retention at the end of two years.

The second patient I operated upon was seventy-three years of age. He had a right lateral hypertrophy, acute retention, and pyonephrosis. He could not endure the passage of a catheter, and therefore most unwillingly submitted to a perineal section. The bar at the neck of the bladder was burned, fragments of the right lobe shedded out, and his symptoms temporarily and partially relieved. As his condition improved after the operation he continued to discharge great quantities of pus from the left kidney and had what appeared to be reflex spasm of the sphincter, for at times he would empty his bladder completely, and at other times would require catheterization. I urged nephrectomy upon him so strongly that he changed his physician and died eleven months after operation of sepsis.

The next patient operated upon was sixty-seven years of age. He had a bilateral hypertrophy, and two to three ounces of residuum. His bar was burned at both ends and the intervening portion removed. His symptoms were thereby relieved for five years. They then relapsed and he had his prostate removed. But as he has continued to suffer from recurring stone in the bladder since that time he doubtless still has some retention. It is now eleven years since his operation, and I have not seen him during this interval.

These three cases illustrate three facts: In the first place, if the retention is not entirely relieved, relapse of symptoms may be looked for (whether the operation done be a Chetwood or a prostatectomy). In the second place, other conditions, such as the pyonephrosis mentioned, may spoil what would otherwise have been a cure. In the third place I required the experience derived from these three cases to learn how to do the operation successfully.

A fourth member of my seven incompletely relieved patients came to me in April, 1908, with complete retention for eight years, due to contracture and a big prostatic abscess. His condition at the time of the operation was desperate. The operation was performed in two stages under local anesthesia, and his satisfactory recovery was little less than a resurrection. Yet, he continued to have about three ounces of residuum, marked nocturnal polyuria, constant edema of the feet, and bilateral pyonephrosis, as demonstrated by pyelography. This did not prevent his giving up his catheter and holding his urine for from two to four hours, night and day, for five years. Then his residuum began to climb again, and he has had to return to the catheter, once a day, for the past few months.

The fifth unrelieved patient was operated upon for contracture in the tenth year of catheter life. Six years later (in his eighteenth year) his residuum was 150 to 200 c.c., he was using the catheter once a day, and his kidneys were obviously giving out. He doubtless died shortly thereafter.

The sixth patient, sixty-four years of age, at the end of three years had the same partial retention as before operation.

It is to be noted in reference to these three cases that all were contractures and therefore unsuited for prostatectomy.

The seventh patient, seventy-three years of age, had complete retention, following a Young prostatectomy. I performed a Chetwood operation on the chance that it might help (though he had no contracture), and did him absolutely no good. He was last seen two years after operation.

INCONTINENCE OF URINE.

My patients who have been left with incontinence of urine by the Chetwood operation number six. Two of these have unimportant and occasional loss of a few drops of urine at seven and nine years, respectively, after operation.

Case 2360. The patient first entered my office in December, 1889, for the relief of nocturnal emissions. He continued to suffer from these, as well as from minor sexual neuroses, and a great deal of headache, and visited the office almost every year until 1899, for the treatment of these conditions. In 1903 he returned with a recent history of difficult, frequent, and imperative urination. Catheterization revealed eight ounces of residuum; the prostate felt normal; there was no history of gonorrhoea or syphilis, nor evidence of stricture, and there was but little pus in the urine. The reflexes were normal. For one year the patient was kept under treatment by the catheter while various futile attempts were made to relieve the retention, but it remained undiminished. Accordingly perineal section was performed on March 12, 1904, revealing a contraction of the whole posterior urethra. This was torn open with the finger to the bladder neck which was burned "at 7 o'clock" for 0.75 cm. No prostatic enlargement was discovered. The patient urinated
but once through his perineum after the removal of the tube on the second day. He left the hospital on the eighth day with two ounces of residual urine, and on the fourteenth day the bladder was emptying itself and he was holding it for periods of two hours. This was by day April 10, 1904. He slept all night; his urine was normal. He lost only a few drops of urine after urination. February 1, 1905. He was much stouter than ever in his life, and perfectly well, excepting for the loss of a few drops at bedtime, and from urination. After dinner he slept for seven hours and occasionally a very slight dampness of his nightshirt. March 15, 1913. His condition was unchanged.

Case 4479. Aged thirty-six years; he had had gonorrhea for three months, with profuse discharge; he voided the urine in the bulb after the first day, and with residual urine amounting to thirty c. c.; an urethral stricture in the bulb grasped a 23 F. sound. The urethra was extremely sensitive, and he suffered many repaired pains. The patient, a physician, was very suspicious. June 6, 1905. Perineal section revealed the stricture, and beyond this a small cavity in the right lobe of the prostate, where an abscess had opened into the urethra; behind this was a moderately tight bladder neck, which was burned. The wound did not heal until July roth, at which time its gonorrheal infection was still moderately active. On September 12, 1906, he had gained forty pounds. The urine still contained some pus and shreds, but there was no urethral discharge. He passed an urinometer twice a day and once a week. On May 6, 1908, the urine contained only a bacterial haze and a careful physical examination revealed no irritation. This incontinence of urine was continued for four and a half years. August 6, 1912, he reported another gonorrhoea in 1911. Urine was clear; he was perfectly well excepting for the occasional loss of a few drops of urine.

Three others were left incontinence of sufficient importance to cause inconvenience. One a year after operation had incontinence only after becoming tired by standing at his occupation for six or eight hours. Another was reported a year after operation as having regained "fairly good control." He died a few months thereafter apoplexy. A third, six months after operation, had some residual by day, and incontinence by night. At the time of operation I suspected this man had carcinoma, and in spite of a gain of seven pounds, the curious combination of retention and incontinence, which was certainly not due to unusual bladder irritability, rather confirmed the tentative diagnosis.

Finally, one case operated on in desperate straits, and whose most important lesion at the time of operation was a pyonephrosis, was left with incontinence of urine and a perineal fistula up to the time of his death from intercurrent disease, two years after operation. Bad as this result was I questioned whether he would have survived a more grave operation, and the drainage of his kidney unquestionably saved his life.

Case 4137. Aged fifty-five years. He had had complete retention three weeks, preceded by a gradual increase of urinary frequency for six months. The prostate was not enlarged. Perineal section revealed a bladder neck too tight to admit even the finger tip; this was divided by a burn on May 3, 1909. Two weeks later the fistula had healed itself. On July 11th he was dry by night and just beginning to get control by day. November 6th: He was dry by night and when sitting down; but he ran an elevator and began to dribble after working three or four hours. A month later, his treatment by instillations had so improved this incontinence that he was absolutely dry until 3 p. m., and also dry throughout the holidays. In May, 1910, he was still better, losing his urine only when tired from long standing.

Case 5731. This patient, aged seventy-four years, was first seen on the day of his operation, at which time he had been depending upon the catheter for three years, since the opening of a prostate abscess into his rectum, previous to which time he had occasionally used the catheter. During his three years of catheter life he had suffered a great deal of inconvenience, on both sides on various occasions, and had several attacks of angina pectoris. November 19, 1905. Perineal section revealed a marked bar at the bladder neck with a right lateral lobe. The Chetwood operation and a double vasectomy were done in thirty-five minutes. After the eighth day he was perfectly well, but a month later his nurse reported "The perineal wound is healed, the bladder empties itself, the testicle no longer relapses, but the urine continues purulent." On January 7, 1906, his physician reported, "The extension of his bladder had a good deal of incontinence, especially when on his feet, and he has to wear a urinal to catch the overflow." A year later his physician reported, "He regained fairly good control and has been pretty comfortable. I think that 'much improved' would describe the result." In March, 1907, he died of apoplexy.

Case 8043. Aged sixty-four years; he had frequent urination for three years, beginning with an abscess that broke into the rectum. He urinates every hour by day, and has incontinence of urine by night. His residual urine is eight ounces, full of pus. He was treated by catherization and bladder washing for ten days with the result that the pus was much less but the symptoms unchanged. He passed "a very feeble discharge" on admission. He was sent to a hospital, phthalein in the first hour, after ten minutes delay. On June 11, 1912, cystoscopy showed a moderate intervesical projection of the left lobe, and perineal section revealed the fact that this lobe was not very large, and that the entire urethra of the patient was double. On the sixth day of a new attempt, the urine was normal. The remainder of the prostate appeared to be normal; the bladder neck was elevated by this lobe and this elevation, or bar, was burned through; a tentative diagnosis of carcinoma being made. He had a fistula closed in three weeks, but left him with some incontinence of urine by day and by night.

On January 8th, six months after operation, he wrote that he was seven pounds heavier than before operation; he could drink his urine from two and one half to three hours; that the rectum was normal, he was doing three courses of the enemas, and that his incontinence by night continued; but that by day he was dry and had no pain on urination.

Case 8737. Aged seventy-one years; six years ago he had acute retention; thereafter slight irritability, until one year ago when he had fever and passed blood, and the bladder became irritable. During the year he lost twenty-five pounds, and three weeks ago the irritability again became intense. For the past three years he had a daily chill, followed by a temperature.

September 14, 1908. Examination revealed a normal prostate; there was a great deal of thick renal pus in the urine; he had a dry tongue, and was in a very poor general condition. The patient was put in the hospital and a perineal section done under local anesthesia. A point of pus and bar was found at the bladder neck, but no other evidence of prostatic hypertrophy. Chetwood operation was done, and the tube was taken out on the third day.

He continued to have chills and fever from his renal infection for many days and extensive sloughing occurred throughout the perineal wound. He left the hospital in five weeks, however, but with a big hole in the perineum, through which he had complete incontinence.

Thereafter his general condition improved very slowly, and, although he continued to have attacks of chills and fever every few months, he was able to work for a year, up to the time of death, which occurred suddenly, after a few hours illness, in December, 1910.

CURES.

Among the fifty-seven patients operated upon, twenty-seven have been followed for a year or more (omitting cases of carcinoma, tuberculosi, and tuberculosis). Seventeen, or sixty-three per cent., of these patients were cured, and the cures verified for nine years in one case; seven years in three cases; six years in one case; five years in one case;
LEWISOHN: ESOPHAGOSCOPY.

A NEW PRINCIPLE IN ESOPHAGOSCOPY.*

BY RICHARD LEWISOHN, M.D.,
New York.

In the past thirty years a large number of physi- cians and instrument makers have busied them- selves with the construction of various types of esophagoscopes and much ingenuity has been ex- pended in the development of different models. The multiplicity of instruments is a proof that no one instrument is entirely satisfactory in every re- spect. The straight tube esophagoscope, as you all know, is the one in most extensive use at present, and this principle of construction is the only one that has proved itself useful. Still one cannot say that the instrument is a popular one. There can be no doubt that in the hands of experts it has given very satisfactory results. Nevertheless the introduction of the straight tube especially into the lower parts of the esophagus is not only not entirely devoid of danger, but very difficult in a large ma- jority of cases, insomuch as the overextension of the head forces the patient into a most uncom- fortable position. For this reason attempts have constantly been made to construct an instrument, the introduction of which would be less dangerous and less disagreeable to the patient. Without dwell- ing here on the various models heretofore con- structed for this purpose, the majority of which have been based on the principle of the jointed tube, I would like to show you here an esophago- scope which I have constructed, based upon an en- tirely new principle, namely, that of a rectangular telescope.

The new features which were strictly adhered to for the first time in the construction of the in- strument are: 1. The introduction is possible in the normal position of the head; 2, the instrument is so constructed that it actually passes in the lon- gitudinal axis of the esophagus, and not at an angle to this axis.

I wish to make the description of this instrument as short as possible, as I hope to have an oppor- tunity to demonstrate it on a patient, and give you then the further details of its construction. It is a right angular instrument, with a light attachment at the proximal end of the horizontal tube and a mirror at the junction of the horizontal and ver- tical parts. The vertical part consists of six tele- scopic tubes, the uppermost of which carries two metal guides. These guides, which act as a kind of obturator, lead the way into the esophagus. It is surprising how easily one can enter, with their aid, the mouth of the esophagus, and anchor the instrument within the upper part of the esophagus. All further manipulations (evolving the telescope, etc.) are, of course, done under the guidance of the eye.

The aspiration of mucus is done either by a piece of rubber tubing attached to a Killian bottle or by means of an applicator. I have constructed in the last few months a forceps which will ultimately make possible not only the excision of specimens for microscopical diagnosis, but also the removal of foreign bodies.

I have used the instrument in quite a number of cases, mostly of cancer of the esophagus.

In trying to compare in an unbiased way this new instrument with the straight tube, I would like to state the following: This instrument was not constructed to supplant the straight esophagoscope. I think that in the hands of experts the straight tube will continue to be a very useful instrument.

The technic of straight esophagoscopie, however, is not easily acquired, and though I have seen a great many colleagues use the straight tube, I have found very few who could master the introduction. The introduction of this new model is, on the other hand, extremely simple, and with the exception of one case where pathological conditions in the up- per air tract were prevailing, I have never had any difficulty in introducing the instrument. Patients who have had the straight tube as well as the telescope passed on them greatly prefer this new model, be- cause it is introduced in the normal position of the head, and avoids the very uncomfortable overex- tension of the head. On the other hand, this new model is not as simple in its construction as the straight tube. Instrumentation through it is some- what more difficult, as all manipulations have to be done over a right angle. Furthermore, for reasons which are self evident, it only brings into view lesions which are more than eight inches from the teeth, and at least in its present construction does not show affections of the uppermost part of the esophagus behind the cricoid.

I started this work a few years ago because I felt that the straight instrument did not meet with the general approval of the specialists, to say nothing of the aversion it still encounters from the general practitioners and the patients. I felt that the unpopularity of the straight esophagoscope was mainly based on the fact that the straight tube does not adapt itself sufficiently to the normal anatomi- cal relations between the mouth and the esophagus. I feel assured that I have succeeded in constructing an instrument which overcomes this objection. Those who are in every way satisfied with the use

*Read before the Seventeenth International Congress of Medicine, London, August 6th to 13th, 1913.
of the straight tube should continue esophagoscopy with that instrument; those, however, who feel that the straight esophagoscope is not a harmless instrument and gives a good deal of discomfort to the patient, I would advise to try this new model. I feel assured that the telescopic model will prove to be a useful addition to our esophagoscopic armamentarium.

I West Eighty-fifth Street.

THE ETERNAL MEDICAL VERITY.

BY W. B. KONKLE, Montoursville, Pa.

Not an eternal medical verity, but the eternal medical verity—the primal truth, the basal truth. Nature is the healer—that is it. Jesuit's bark and quicksilver with its latter day ally or competitor, arsenic, do not negate the great verity. Ordinary therapeutic agents and measures so multiform and manifold do not cast doubt upon it. Vaccines, serums, and organic extracts only corroborate it. Beyond this a thousand things establish it. Through his journey down the years closely by his side Nature walks with the individual, her agis over him, unrelaxingly watchful, toujours en vedette, lifting him when he falls, rescuing him when he is assailed. And his heart beats on, and his brain acts, and his senses receive, and his members put forth strength. Nothing derogatory to his protectress is it that certain of his foes are stronger than she.

Nature recks naught of the lamentable fact that of his physical enemies man is himself the worst. Through her benign and masterful ministrations, in spite of himself he survives the ages. Yet, nevertheless, the case remains that most of her weaknesses and failures, manifest or seeming, are due to his own suicidal, self annihilative customs and habits. But in such contingency surely Nature is not at fault. Let not the results of errors of fashion and conduct be attributed to impotence or lapse of function upon her part. For instance, let there not be charged to her the sins of the corset as a cause of pelvic derangement and of impairment of the hepatic and mammary glands. Indeed the most common ground of Nature's so called failures, as well as the largest field of opportunity for science and art in therapeutics, is where Nature has been priorly diverted or perverted or inverted or obstructed.

Nature at times and in places seems to blunder and fail because she works by the process of gradual development, rather than by immediate change. She does not leap to her ends, but guardedly, deliberately approaches them. She does not peremptorily cast out of date means and methods, and instruments aside, but slowly effaces them. Evolution is her method; not instantaneous, outright creation or obliteration. She keeps on running over the bridge while the old structure is little by little being transformed into new.

And, too, Nature may seem remiss, even perverse, where she is in reality energetic and consistent as judged by the criterion of her aims and plans. One of her highest, worthiest designs is the survival of the fittest. Logically, inevitably the means to that end is the elimination of the unfit. And in this light to Nature will be ascribable full success when otherwise viewed she might be deemed accountable of slackness and defect.

Among the prerogatives and offices of the present day healer is eminently included prophylaxis. Indeed this has come to be esteemed the most prominent and promising department of medicine. And Nature, too, is par excellence the preventive healer, paradoxically speaking. Here she is at her very best and queenliest. Here she operates marvelously. In example germs as disease factors may be cited. When they and their role in pathology were discovered with affluent scientists meditated their absolute exclusion from the organism as a measure expedient, even imperative. And then, lo! it was found that Nature had anticipated the necessity, and had established a system of defense charmingly effective. Aye, a far sighted, tactful Frau is this same Mistress Nature, who saves herself as a healer a lot of aftercare and effort by nipping trouble in the bud. Not she the one to leave the macrobe helplessly and hopelessly exposed to the onslaughts of the microbe. Also through victory itself temporarily won by the latter she provides double armament against any future attack.

Our fundamental principle of vis medicatrix naturae has not, however, come down the centuries unchallenged. No tenet is so exempt from antagonists that it may walk abroad without sword and shield. The great Erasistratos himself, in contrast with his equally great contemporary Herophilus, led off in dissent from the Sage of Cos. He did not wholly repudiate Hippocratism; but he rather completely divorced himself from vis medicatrix naturae. Then in legitimate line from the illustrious Alexandrian we come to Asclepiades of Prusa, the forerunner of the Methodists. The Bithynian was the arch adversary of Nature the healer, stigmatizing Hippocrates' attitude of expectancy and subordination as a "meditation upon death." He says, "In disease Nature as often works injuriously as beneficially." But Asclepiades was better than his creed. In practice he employed the very agencies of Nature which he spurned in theory. Practically a wise, skillful doctor, he rendered the decadent Roman aristocracy most valuable and acceptable service, instilling as was his wont into his therapy the spirit of his own famous maxim of "nullo, celeriter, ac iucunde." His followers all along the way into modern times espoused his feud against vis medicatrix naturae. In later days Cullen like the ancient master sharply distinguished between theoretic views and practical indication, and in consequence is accorded enviable renown as a physician. Hahnemann was harmless. Brown and Broussaix translated their pernicious theories into practice. They were as bad as their bad creeds.

Even to-day Nature has her contemners. Yet at this late hour occasionally is heard the echo of the Bithynian's voice—"In disease, Nature as often works injuriously as beneficially." Such detractors of Nature, goddess whose nude form is radiant with vigor and chaste loveliness, regard her as vacillating, frivolous, and wanton. They would say to her, Put on your clothes, you old hussy! and
be conventional and regular and orthodox, as a dame of your age and standing should be!

At the other pole of thought as pertaining to the principle of *vis medicatrix naturae* is found the new Vienna school. Of this Olympus Skoda is the Zeus. As marked as its *p penchant* toward accuracy of diagnosis was the school’s therapeutic nihilism. The matter of cure was unconditionally left to the tutelage of Nature who might seek in vain for a handmaid in Vienna medicine. To diagnosticate and prognosticate, that was about the sole office of the physician. Undoubtedly a patient would be content, would feel that he had gotten all that he could wish or ask, when he was told what was the matter with him, and whether or not he was going to die. To be sure at the outset he might find himself in the sentiment of one of Molière’s characters who soliloquized thus: :

“*Je tremble du malheur qui m’en peut arriver, Et l’on cherche souvent plus qu’on ne veut trouver.*”

And then, of course, he might, too, as his case proceeded be taken with some longing for medical help. Such a mental attitude would not be at all strange since the infallible Galen himself says: “*Populus remedia cupid!*”

But of the forming and directing minds that from the beginning and throughout have swayed the destinies of medicine, so far as we know a majority overwhelming have stood for the idea of *vis medicatrix naturae*. Haëser says that Bouchut, a contemporary of Hippocrates, wrote upon the healing power of Nature. We, however, are accustomed to look to the immortal Coan as the chief exponent and exponent of the principle in question. Hippocrates did much for medicine. He led the healing art forth from its temple prison into the free air and under the broad sky. A French scholar remarks that as Thucydides banished the marvelous from history so Hippocrates banished it from medicine. He insisted that observation rather than speculation constitutes the true instrument of progress. And with a charm and grace unmatched and all his own he taught how to observe and how to record. He, besides, established individualization in practice. These things he did. But a still more important service to his art was his earnest and eloquent announcement that the healer is Nature, and the physician is her servant, not her teacher. This is naturism. This is Hippocratism. And as Bouchut aptly states, “After two thousand years of observation, of experience, and of controversy, the naturism of Hippocrates yet stands upright.”

Under the therapeutic banner unfurled by the peerless Son of Cos with ranks unbroken the grand army of medicine has marched along the track of the intervening centuries. Herophilos, taught of the Coan Praxagoras, held it aloft. The Empirics, of whom Heraclides of Tarentum was the most distinguished, sturdily bore it far. Aretaios of Cappadocia, truest of Hippocratis, maintained it intact and unsullied. Thus strong, leal hands have ever welcomed, ever defended, ever carried forward the standard raised by the lord of the little Ægean isle. And thus was it passed on and on and on. The list of those great banner bearers is long. Only a few more such representative names may be mentioned. Standing for Rome there was Celsus, dignified by the twofold title of Latin Hippocrates and Cicero of medicine. And there was the Pergamanian, Galen the unique, rare encyclopedist, autocrat of his guild for a thousand years. And there was Oribasius, another Pergamanian, friend and physician of the Emperor Julian. And then followed in order the illustrious Arabs, who received from the Syrian Jews and Nestorians the torch of Greek thought and learning and with it illumined Asia, Africa, and Europe. And then came Paracelsus, the Luther of medicine, whose motto was, “*Qui suus esse potest, non sit alterius.*” And there was Fernel, the scholar, schoolmaster in the medicine of the renaissance. And there was Paré, who adopted as his device, “*Je le pansay, Dieu le guérit.*” And afterward came Sydenham, Hippocrates redivivus, a very titan among the men of the healing art. And then came Boerhaave the erudite, the most famous doctor in the world, he who made Czar Peter the Great wait his turn with numerous other patients. And then follow down to the present naturalists and naturists a brilliant host.

But if adherence to naturism has been so general and continuous, if it has been so constantly held as the touchstone or loadstar of medicine, what important purpose can be served by its reenunciation? If the principle may to-day be considered a threadbare truism does not its representation smack of the platitudinous? Its iteration and reiteration is warranted by a single significant circumstance. While acknowledged academically, the principle has been in practice violated in one way or another at all epochs and by its ablest exponents. Again and again has naturism been wounded in the house of its friends—unintentionally so, unconsciously so. Hippocratism has been dishonored by Hippocrates. Such transgression occurs either through application of faulty theory or by the misinterpretation of a fact not perceived in all its bearings. The fallacy will best be avoided by frequent reference to the great, basic principle itself, *magna charta of the healing art*, as in “Pilgrim’s Progress” Christian persistently consults his roll on his way to the Celestial City.

Yes; Hippocrates himself who saw so keenly and so clearly became so ensnared by his humoral pathology, his doctrine of coction and crisis and his adaptation of the Pythagorean system of numbers that at many points he widely departed from his own naturism. The mistakes of the master incessantly reappear in the practice of his followers. Theories, systems, assumptions so befog the field that genuine, vital Hippocratism is largely lost from view. A Will-o’-the-wisp chase is kept up after the essence of the *vis medicatrix naturae*. Ontological speculation supersedes phenomenal observation—it is sought to know what can not be known. In this mad endeavor to drive Nature into a trap it is forgotten that whoever or whatever she may be she still is the healer. And thus the wisest heads have been turned and the most skillful practice has been marred. And it has been found necessary to hark back to naturism pure and simple, and from there to start afresh.

Even with the advantage of vastly expanded knowledge and the possession of a long record of
errors we yet lack caution in divining natural indication. Within easy memory we indiscriminately depressed elevated temperature. We know better now—know that fever is often beneficent. Just now we are in danger of making the same faux pas with reference to blood pressure. When shall we learn that to suppress a symptom is not to remove disease? When shall we cease to act upon the policy of the ostrich who thinks herself amply protected when she has thrust her head in the sand?

From this review some lessons may be deduced. And first of all and above all, in whatsoever we do we should be as sure as may be to contravene no natural process. We may aid as we can, at times may even take the initiative, but must strive to not antagonize Nature—must, so far as possible, and as soon as possible relinquish to her the arena. It is true she is both resourceful and benignant; and when we get in her way she manages to step around us or over us. But that furnishes no excuse for our getting in her way. Particularly careful should we be to not meddle with normally progressing operations. Meddlesome practice is like bothering a brooding hen. Biggby, though not a philosopher, though not knowing much beyond laying and hatching eggs, is yet in her line an inspired hen—as much inspired as Moses or Socrates. And the doctor should bear in mind that no matter how great his services in a case may be, Nature does still more. The Blicher of a Waterloo should not take on the airs of its Wellington.

In his management of disease the physician should closely study natural indications. He should remember that theory belongs to the science, not to the art of medicine. In the “Odyssey” occurs an expression like this: “He has told many lies in telling things seemingly true.” Theorization is exceedingly liable to come to about that. Herophilus declared that when properly employed medicines are “the hands of the gods.” Their proper use, however, presupposes thorough scrutiny of the conditions. In any case before attempting to modify alterations of function the meaning of such alterations should be accurately interpreted. Otherwise justification might be found for this cynical statement of Wedekind: “The value of medicine, expressed in two words, consists chiefly in this, that civilized nations have to suffer far more from their physicians than from their diseases.”

Natural indication should have its influence in the determination of the direction of investigation. What sense is there in a quest for means to accomplish things that can not be accomplished? This proposition is tentatively put forth: What Nature does not do sometimes upon her own initiative, of her own free will and accord, that she cannot be forced or coaxed to do at any time. Such rule if it has any value will be especially applicable to the cancer problem. At any rate, prophylaxis is the Promised Land where medicine hopes at last to dwell. And it is a safe prediction that never will a time come when perfection of artificial cure will render neglect of the prevention of disease a matter of indifference and unimportance.

Not to effect striking cures of incidental sickness, but to make people comfortably and enjoyably live out their three score years and ten or four score years is the true end of medicine. Comfortable and enjoyably live advisedly we say, because good living is a higher mark than long living. Says Seneca, “Non vivere bonum est, sed bene vivere;” of which maxim another form is “Dum vivimus vivamus.” To this end let the physician ever entertain and cultivate confidence in, and respect and veneration for, the laws of Nature. The Ecclesiastist says, “Let us hear the conclusion of the whole matter; Fear God, and keep His commandments; for this is the whole duty of man.” Slightly paraphrasing the text it may be addressed directly to the members of the healing art: Let us hear the conclusion of the whole matter: Revere Nature and sustain her laws: for this is the whole duty of the physician. Here and there, forsooth, a thunderbolt blasts a kingly oak; but the mighty world girdling electric tides in unbroken silence steadfastly keep their equipoise. Now and then the storm lashed sea swallows up some gallant ship; but the life bearing currents of old ocean without pause or sound through unfathomed depths majestically sweep on. The meteor shoots out to extinction in the blackness of darkness; but the everlasting stars in their courses never fail.

“And were the world below content to mark And work on the foundation Nature lays, It would not lack supply of excellence.”

(Dante, Cary’s translation.)

**EOSINOPHILIA PRODUCED BY HYPODERMIC INJECTIONS OF CROTALIN SOLUTION.**

*Its Value as a Guide to Dose and Frequency of Administration.*

**By Ralph H. Spangler, A.B., M.D., Philadelphia,**

Chief of Medical Clinic, Methodist Episcopal Hospital.

Since the hypodermic use of crotalin solution was introduced as a therapeutic agent about five years ago, much has been learned as to its action on the human organism. There still remains, however, much to be perfected as to the best method of preparing the solution, and the strength of dose suited to varying individual idiosyncrasies needs further investigation. It is, moreover, of the greatest importance to determine a scientific method of regulating the dose and the frequency of its administration.

The writer’s personal experience with crotalin has been largely confined to its use in cases of epilepsy, and careful records have been kept of two hundred and fifty-two patients treated in private practice. Furthermore, correspondence with a large number of physicians, seeking information in reference to the use of crotalin, has made it seem of value to report my recent experiences and observations, with the hope of developing additional information in regard to its physiological action and therapeutic value.

**Care in Preparation of the Solution.**

Crotalin being an albuminous substance, it is impossible to sterilize it with heat. It is, therefore, necessary to add to a solution of crotalin some anti-
septic. In the writer’s experience the most satisfactory preservative and antiseptic for this purpose is trikresol. The venom is extracted from the living reptile, *Crotalus horridus*. The evaporated, dried, yellowish crystals of the venom are dissolved in sterile water and glycerin, to which is added enough trikresol to keep the solution sterile. This solution is prepared in varying concentrations and put into sterilized ampoules containing one c. c. each, representing 1/400 grain, 1/200 grain, 1/100 grain, *et cetera*, according to the dilution desired by the physician. A bacteriological test of each new lot of ampoules is made to determine freedom from aerobic and anaerobic contamination. Plates of agar agar are also made in addition to the other tests and allowed to incubate for seventy-two hours. Thus danger of infection from the solution is practically eliminated.

**TECHNIC OF GIVING INJECTION.**

It has seemed best to use an all glass, aseptic, hypodermic syringe and a platinoridium needle, about one and a half inches in length. The syringe is sterilized by cleansing with alcohol and boiling. The needle is heated over a Bunsen flame or boiled. After breaking off the neck of the ampoule the crotalin solution is drawn into the syringe and after expelling the air, is ready to be injected.

The site of injection is cleansed with tincture of green soap and alcohol, or touched with tincture of iodine. The needle should be well introduced into the muscles (intramuscular), at an angle of about sixty degrees, and the contents of the syringe expelled slowly. After withdrawing the needle the wound is covered with a little sterilized cotton and collodion, or Turlington’s balsam.

**SITE OF INJECTION AND LOCAL REACTION.**

It has been my practice to give the injections in the supinator group of muscles of the forearm, as a rule using the right and left arm alternately. The degree of local reaction obtained varies with the individual susceptibility of the patient. In most cases the patient complains of a slight burning or stinging sensation at the site of injection, and this sensation frequently radiates for a few inches up and down the forearm. This discomfort lasts but a few minutes, and no further effect is noticed for from two to six hours, when a swelling and slight erythema appear. The degree of cellulitis thus produced varies greatly in different subjects, and a decided variance in susceptibility is often shown from time to time in the same individual. In the average patient the maximum amount of local reaction is obtained in from twenty-four to thirty-six hours after an injection, and by the third or fourth day the part, in which the injection was given, will usually have regained its normal condition.

The forearm has been chosen as the site for the injection so as to avoid the involvement of the shoulder joint, in case the patient shows undue susceptibility or an excessive cellulitis is produced. Moreover, it is very convenient to apply to the forearm an icecap or a saturated solution of sulphate of magnesia, on layers of sterilized gauze, if the patient complains of much inconvenience from the reaction, so that it is necessary to use a local application.

**THE DOSE.**

In the average adult case I usually give 1/400 grain of crotalin in solution at the first injection. In children, anemic adults, or plethoric subjects, I frequently use only 1/600 grain for the initial dose.

The second treatment should not be given until all evidence of local reaction from the first injection has disappeared. As a rule it is best to wait at least seven, and in some instances ten, days before administering the second dose. The strength of dose at the second treatment should never be larger than at the first treatment. In nine out of ten patients the small second dose produces but slight local and no systemic manifestation, but one out of ten or twelve patients, occasionally, will exhibit evidence of oversusceptibility. Thus, if the strength of the second dose is increased, and any anaphylactic tendency is present, a severe local and profound systemic reaction will result. Quite naturally the question arises—is there any scientific method to guide the physician in regulating the strength of dose, and the frequency with which the injections should be administered in a given case?

**THE EFFECT OF CROTALIN ON THE BLOOD.**

For the past year I have been watching very carefully the effect of crotalin solution injections on the blood count. The statement has been made that the crotalin treatment should not be used because “all venoms have a hemolytic effect.” In a series of 161 cases, in which complete blood counts were made after administering crotalin solution, for periods of from two to six months, there was absolutely no hemolytic effect produced, as evidenced by no reduction in the number of red cells, no crenation of the same, no decrease in the percentage of hemoglobin, nor evidence of hemoglobinemia. On the contrary seventy-five per cent. of these patients, after having their accustomed quantity of bromide much reduced or entirely withdrawn, showed an increase in the number of red cells and the percentage of hemoglobin, after a course of several months’ treatment with the crotalin solution.

It has been suggested that crotalin influences epileptic cases by producing a leucocytosis. In the above referred to series of 161 cases, the leucocyte count in ninety per cent of them was never over 8,000 or 9,000 and the highest leucocyte count in the remaining ten per cent. of the series was 12,500.

**EOSINOPHILIA PRODUCED BY CROTALIN.**

While crotalin does not produce a leucocytosis, it does have a marked influence on the differential leucocyte count. Careful records have been tabulated in fifty-seven cases in which, from six to twelve or more differential counts were made over periods of from three to six months in each case. This series shows very conclusively that crotalin has a decided tendency to produce an eosinophilia. Moreover, the susceptibility of the individual to crotalin can be determined by the degree of eosinophilia produced. From forty-eight to seventy-two hours after an injection of crotalin solution, depending on the susceptibility of the patient, the proportion of eosinophiles will often be increased to from eight to ten per cent. In more susceptible individuals they are often increased to fifteen or
DIREFTIAL LEUCOCYTE COUNT A GUIDE TO DETERMINING THE STRENGTH OF DOSE AND THE FREQUENCY OF ADMINISTRATION.

It should be a routine practice when beginning the treatment of a patient with crotalin solution, to have a complete blood count made and the percentage of hemoglobin estimated before the first injection is given. From thirty-six to seventy-two hours after the injection, when the local reaction has reached its height, another differential count is made, noting especially the increase in the percentage of eosinophile cells. Clinical experience seems to indicate that it is best not to have more than an eight to ten per cent. increase in the eosinophiles in most cases. As a rule in from six to eight days after a treatment the eosinophile cells will have dropped to two or three per cent. To be sure that the differential count has returned to near the normal, another differential count is made before giving the next treatment. It is advisable always to make the two differential counts between treatments, but it is imperative that a second be made if the eosinophilia has been above twelve per cent. at the height of the local reaction (seventy-two hours). In patients with oversusceptibility, as indicated by a thirty, forty, or higher percentage of eosinophilia, a subsequent treatment must not be given until the percentage of eosinophiles has returned to about the normal. Occasionally I have felt it advisable to wait as long as three weeks between treatments, in cases showing a marked eosinophilia from the crotalin solution injections.

It is my practice not to increase the strength of dose as long as an eight to ten per cent. eosinophilia is produced. This is true even if very slight local reaction is obtained. My past year's experience would indicate that it is far better to regulate the strength of dose by watching the differential leucocyte count, than to depend on the degree of local reaction obtained. I have records of cases where the dose has never been above 1/200 grain, and the local reaction very slight. The average patient requires a treatment about once in seven to ten days, and it is usually necessary to gradually increase the strength of dose to 1/100 grain, or in some instances to 1/75 grain. Rarely, however, have I

found it necessary to give as large a dose as 1/50 grain in order to have an eight to ten per cent. eosinophilia produced. It has been more than a year since I have given so large a dose as 1/25 grain, and I would at this time especially caution against large doses. During the last two years three fatal cases have been reported to me by physicians from different sections of the country. In two instances the strength of dose used was 1/25 grain, and in the other case 1/15 grain was given. In previous articles (New York Medical Journal, September 14, 1912, and April 5, 1913) the chemistry of crotalin was discussed, and its effect on the clotting time of the blood pointed out, with detailed reports of patients treated. Reprints of these articles will be furnished to physicians upon their request.

Below is appended the history of a patient re-
cently treated, and the form of office record kept of private patients. This includes the date of each treatment, the strength of dose, site of injection, the degree of local reaction, the clotting time of the blood, together with the differential leucocyte counts made from time to time.

CASE. B. T.; male; aged thirty-nine years; single; occupation, broker.

Chief Complaint: Major and minor epileptic seizures.

Family History: Mother died at sixty-five years of senile dementia; mother's brother had grand mal; one maternal uncle was an epileptic; mother's sister has an epileptic daughter. Father living and well; one brother died in childhood; one brother living and well. Previous Personal History: Second in order of birth; full term child; normal, spontaneous birth; bottle fed infant. Cut teeth, talked, and walked at usual age. Measles in childhood. No accident, injuries, nor operations. Specific history negative. At twenty-one years, after a long, hard bicycle ride, had a convulsion at night accompanied with tongue bite and incontinence of urine. Epileptic History: One month after convulsion this patient had a second convulsive seizure (diagnosed epilepsy). These attacks continued at about monthly intervals ever since. The longest interval between attacks had been two months under bromide treatment. Had never had more than one attack in twenty-four hours. Record of major attacks for 1913 was as follows: January 8th, February 7th, March 9th, March 15th, April 16th. Between these major attacks would occur, at irregular intervals, mild seizures of petit mal. The Major Attack: No describable aura, moan, or cry; tonic followed by clonic convolution; biting tongue; stertorous breathing with frothing at the mouth; occasional incontinence of urine; went to sleep; woke up with headache and felt very dull the next day.

Minor Attacks: These occurred at irregular intervals between the major seizures and vary from momentary lapses of unconsciousness to various forms of automatism.

Physical Examination: Weight, 187 pounds; height, five feet eight inches; reflexes active; station and coordination good; pupils react normally. Heart and lungs negative. Slight amount of albumin and a few hyaline casts in the urine. Always more or less constipated.

THE USE OF THE PHARYNGOSCOPE BY THE GENERAL PRACTITIONER.

By Harold Hays, A. M., M. D.,

New York.

Assistant Surgeon in Otolaryngology, New York Eye and Ear Infirmary.

Since I devised the pharyngoscope in 1909 (described at that time in The Laryngoscope, American Journal of Surgery, and New York Medical Journal during that year), I have had the pleasure of seeing it grow in popularity until to-day it, or some of its modifications, is used universally. I have had letters of commendation from physicians in almost every country and feel that these have been sufficient reward for the time and labor spent in perfecting it. Although during the past four years I have in no way changed the original instrument, I have learned a great deal from its use and will take this opportunity to present my experiences, believing as I do that the instrument has come to stay.

For those who are not acquainted with the instrument, a brief description of it will suffice. The pharyngoscope was first designed to give me a better view of the nasopharynx, but it was only a short time before I was assured that it could be used for examination of the larynx as well, particularly in those cases where a mirror or the direct laryngoscope could not be used.

The pharyngoscope (see illustration) is composed of a horizontal and vertical shaft which join each other at right angles, at the outer third, so that the instrument may be used as a tongue depressor. The inner portion of the horizontal shaft consists of a central circular tube with an electric light carrier on either side, the three components being incorporated in a flat piece of metal. From the inner end project the two electric lights which are water tight, give an intense illumination, and become only warm enough to keep vapor off the lens. In the central tube is inserted the telescope, which is made on the principle of the Otis cystoscope. To the eyepiece is attached a little metal ball which indicates the position of the lens. This horizontal shaft, including the telescope, is about eight inches long. The widest portion of the instrument, which is at the extreme inner end, is less than five eighths of an inch, and the flat metal shaft itself measures less than one half an inch in diameter. The vertical portion is about six inches long and half an inch wide. It is attached to the horizontal portion by a screw joint, and contains the wires for connection with the rheostat or dry cells. Near its upper portion is an arrangement for cutting off the electric current so that the lamps need not be turned on until the instrument is in the mouth.

The instrument is inserted into the mouth like a tongue depressor until the inner end of the telescope is about one sixteenth of an inch from the pharyngeal wall. When once in place it is held firmly by the examiner and the patient is told to close his mouth and breathe quietly through his nose. As soon as the mouth is closed, it is observed that the muscles are relaxed and that the nasopharyngeal space is much enlarged. An excellent view of the parts to be seen can be obtained by gazing through the eyepiece of the instrument.

There are four points that are of a great deal of importance in the use of this instrument:

1. The illumination must be as great as the lamps can stand.
2. The lights should not be turned on until the instrument is in the mouth.
3. The lamps should not touch any part of the throat.
4. Every manipulation should be made gently, but firmly.

Many men have not been able to get sufficient illumination because they have used a 16 candle power lamp instead of a 32 candle power lamp on the rheostat. The former cannot be turned down enough to give sufficient light. Of course, where dry cells or a wall plate is used, no trouble of this kind occurs.

The lights should not be turned on until the instrument is in the mouth. The throat reflexes are very delicate and therefore the nervousness of the patient is greatly exaggerated if he sees two burning lamps going into the throat, no matter how much assurance one gives him that they do not get hot. On the contrary, if the lamps are not lighted until out of the line of the patient's vision he imagines that only an ordinary tongue depressor is being used.

The third point is of equal importance, for a sensation of warmth in the throat is liable to be exag-
gerated. If the patient should persist in changing his position so that the instrument cannot be held steadily in the mouth, it is better to remove it and try the procedure again.

The success which one attains in using such an instrument as the pharyngoscope depends greatly on the gentleness and the dexterity of his manipulations. I have seen men poke the instrument into the mouth with such clumsiness, even brutality, that after examining hundreds of cases I am sure they would never be successful in making any lengthy study. (Buffalo Medical Journal, February, 1910.)

I have not modified my original description of the instrument. Since that time I have examined thousands of patients with it with very little trouble at all. I at first described in numerous papers views of the nasopharynx and larynx. But it is not in the usual cases, the simple and easy ones, that one needs an instrument of this character, and although it was originally meant for laryngologists, its field of usefulness is with those men who do not examine these parts regularly and need a special instrument to make their diagnosis a simple matter.

The principal things one wishes to see in the nasopharynx are abnormal growths, the Eustachian tubes, the fossae of Rosenmüller and the posterior tips of the inferior turbinates. All of these can be readily viewed with the pharyngoscope and studied for a sufficient length of time if one uses an ordinary amount of care. I have used the instrument innumerable times in children for the diagnosis of adenoids, and have saved many a child who was a mouth breather from an unnecessary operation—by seeing that he had no adenoids, where by the ordinary examination with the finger, I would have thought I had discovered some abnormal tissue. The obstruction in these cases was due either to something in the nose or a high arched palate. (Journal of Ophthalmology, Otology, and Laryngology, August, 1909.)

The general practitioner, as a rule, finds a great deal of difficulty in using the rhinoscopic or laryngeal mirror. The former even where used properly gives a very restricted view and the latter is rather difficult to manipulate. Often times the medical man wishes he were in a position to diagnostically pathologic conditions of these parts, and he can readily do so with the pharyngoscope. Professor Simpson (The Laryngoscope, August, 1910) says: “It is surprising how, by its use, even in very young patients, a complete picture of the vault of the pharynx may be obtained, thus doing away with the annoyance of digital examination and the difficulty of the ordinary rhinoscopic mirror. In older patients, to those who are not expert in the use of the rhinoscopic mirror, the use of the Hays’ pharyngoscope reduces the examination of this region to comparative simplicity. Among its benefits may be mentioned the mapping out of various hypertrophies and adhesions about the fossa of Rosenmüller and their removal under vision, through the anterior nares with the pharyngoscope in situ.” Although the examination for adenoids in children is one of the most important things the general practitioner has to do as far as the throat is concerned, there are numerous other pathologic conditions of the nasopharynx with which he ought to be cognizant. Many cases of catarrhal deafness and chronic ear suppuration are due to pathologic conditions around the Eustachian tubes which can easily be rectified if they are once seen. I refer particularly to small adenoids and adhesions in the fossa of Rosenmüller which interfere with the muscular action of the tubes. Many a case of deafness in later years could have been cured if the family physician had only been able to recognize the cause of the condition in the nasopharynx.

Another important symptom due to nasopharyngeal abnormalities is a constant hacking cough. This may be due entirely to chronic irritation, or a growth, or less commonly to a band or adhesion extending from the soft palate to the pharyngeal wall. I recall distinctly one young woman who had had an irritating cough for years. She had been examined and treated by numerous specialists without relief. On inserting the pharyngoscope I saw very plainly a band of fibrous tissue about two centimeters long by a quarter centimeter wide extending from her soft palate to the pharyngeal wall behind the Eustachian tube on the left side. By breaking down this band with my finger, her cough entirely disappeared.

Very few men are conversant with the use of the laryngeal mirror, yet how often it is necessary to get a good view of the larynx! It is to those men that I particularly commend the pharyngoscope, for no one can help seeing the larynx with this instrument in almost every case. The instrument is used in the same way as for rhinoscopic examination except that the lens is turned down instead of up. Often times one gets a better view if the mouth remains open, or the tongue may be held by the examiner in the same way as when using the mirror. Applications of various medicaments can be made easily, by passing the applicator alongside of the instrument. With the mirror, as one knows, the view of the larynx is at an angle and therefore the manipulation of an instrument is particularly difficult. The view with the pharyngoscope is direct. Therefore in inserting an operative instrument, one can attack directly the part in view. I have made frequent applications to the larynx in this way and Glogau (The Laryngoscope, October, 1911) reports the removal of a laryngeal polyp by this method. The patient stood the mirror very poorly even with
coca!e anesthesia and would not allow the direct laryngoscope to be used. An operation with cutting forceps and pharyngoscope was readily done. He sums up as follows: 1. There are cases of extreme nervousness, where the mere touch of the laryngeal mirror prevents any operative interference on the larynx, even after thorough cocaineization. 2. Intralaryngeal operations under guidance of the pharyngoscope is of great value, as it contains the advantage of the direct laryngoscopic picture with comfort to the patient. 3. While this method is not destined to replace all others now in vogue, it will be valuable in selected cases. 4. In intralaryngeal manipulations, like probing, etc., this method will, on account of its advantages, find a place in the technic.

I cannot too strongly emphasize the fact that the general practitioner should perfect himself in the technic of laryngeal examination, whether by means of the mirror or the pharyngoscope. There are many cases of hoarseness or cough which are diagnostic of laryngitis without the larynx ever having been seen. Very often the case is not a simple one, but the beginning of a tuberculous condition or carcinoma. How many patients could have been saved or at least made more comfortable if a proper diagnosis had been made at the beginning of the ailment! If a physician cannot master the technic of using a laryngeal mirror, he can learn to use a pharyngoscope with no trouble at all. Once he has seen the larynx to his satisfaction it will be a pleasure to him to examine all other patients with laryngeal symptoms. To my mind the pharyngoscope is of as much value to the general practitioner as it is to the specialist, and it is for that reason I have more directly addressed my remarks to the man who first sees the patient, and who can make himself far more proficient by using the newer diagnostic aids.

II West Eighty-First Street.

PEDICULOSIS CAPITIS AMONG SCHOOL CHILDREN.*

By JACOB SOBEL, M.D.,
New York,
Borough Chief, Division of Child Hygiene, Department of Health.

In the medical inspection and examination of school children three varieties of pediculosis are encountered, in the following order of frequency—pediculosis of the scalp, pediculosis of the body or more properly of the clothing, and pediculosis of the eyelids.

There is scarcely a school in any section of a city or town in which some cases of pediculosis capitis will not be found, either in the form of the pediculi themselves or in the form of their forefathers—the nits in various stages of development; and it suffices to say that all public and other schools in every city have their quota in varying degrees of severity, and in percentages ranging from one to seventy. Those of us who have had to deal with this problem in a city like New York, which, because of its cosmopolitan character harbors a heterogeneous people, of different and often contrary ideas as to mode of living, customs, cleanliness, hygiene, and sanitation, have tried hard and long to effect ways and means whereby pediculosis capitis, I might almost say the nit plague, could be eradicated. After a study of this perplexing problem from many viewpoints and for many years, and after a practical application of many methods hereafter to be enumerated, much has been accomplished. But we are still far from a satisfactory solution of the situation. In discussing the various phases of medical inspection a member of our medical corps frankly said to me “pediculosis capitis is a dead issue.” When one considers, however, that “a single female pediculus will have five thousand descendants in eight weeks,” the question appears a real live one. On the other hand, a school principal not to be outdone by the medical inspector in an opinion of the hopelessness of nit eradication told me “the inspector may come and the nurse may go, but the nits seem to increase forever.” These statements of inspector and principal are evidence of the magnitude of this problem and show how little encouragement workers in this field receive, despite the enormous energy which they exert for the control of the condition.

The following questions suggest themselves: Why does pediculosis capitis assume so much importance as to require constant and unrelenting efforts for its eradication? Wherein lies the difficulty of controlling this condition? Why have not better results been obtained? Why are so many cases still extant among school children? Is it to a consideration and discussion of these questions that I invite your attention, in the hope that the presentation of our observations may perhaps aid others and with the expectation that the experiences of others will prove of lasting benefit to us.

Pediculosis capitis among school children assumes major importance from several standpoints:

1. From the cosmetic side: Pediculosis in any form is a dirt disease and, as such, is a forerunner of illness in its many phases. It is an index of the family's cleanliness, of the parents' care and attention, and of often of the character of the school child. The presence of pediculi in the home, on members of the family, or on the school child may be an accident; their continuance means a disregard for cleanliness and health.

2. Pediculosis capitis acts as an indirect causative agent of local and general pus infections, glandular involvements with subsequent suppuration and scarring, and possible predisposition to tuberculous adenitis; it often means secondary insect-po
taneous dermatitis, furunculosis, eczema, ulceration, folliculitis, and plica polonica.

3. Scalp pediculi are probable carriers of disease: Though not proved absolutely, the presumption is fair, that the pediculus capitis can and does carry disease, just as the body louse carries typhus, the domestic fly poliomyelitis, typhoid, tuberculosis, and dysentery, etc., the flea bubonic plague, the mosquito malaria and yellow fever, the bed bug kala azar, relapsing fever, and anterior poliomyelitis (Howard and Clark, Journal of Experimental Medicine, XVI. No. 6, 1912), the tick, Rocky Mountain spotted fever. Goldberg and Anderson (Public Health Re-
ports, No. 74) state that "the head louse (pediculus capitis) may become infected with typhus. The virus is contained in the body of the infected louse and may be transmitted by subcutaneous injection of the crushed insect and we believe also by its bite." On the other hand, Howard and Clark, in their investigation with the pediculus capitis as a carrier of anterior poliomyelitis, say (The Journal of Experimental Medicine, XVI, No. 6, 1912) "Lice (pediculus capitis and pediculus vestimenti) have not taken the virus out of the blood of monkeys or maintained it in a living state." Experiments with head lice are by no means closed, and the last word as to their status as carriers of disease has not been spoken.

4. Pediculus of the scalp disturbs the general health by causing itching, restlessness, insomnia, irritability of mind and body and as a result of all this anemia and a general lowering of the body tone.

5. Pediculus of the scalp is a transmissible condition which causes suffering and disease in others, and prevents them from following their vocation.

6. The existence of pediculosis interferes with the child’s education because of enforced exclusion from school for varying periods.

7. The presence of pediculus capitis often interferes seriously with the child’s mental equilibrium, in that it subjects him to the taunts of his classmates and in this wise produces a profound nervous depression.

The eradication of pediculus capitis among school children in New York City is rendered extremely difficult, if not well nigh impossible, largely because of the migratory character of its population. Were our people to remain stationary for any great length of time—a condition which obtains in most of the continental cities and in many of those in the United States—the education of the public would very materially help to control this condition. With us, however, no sooner have we educated the parents and children of one section, no sooner has this condition been controlled there, than these people migrate to another city or to another part of our own city, and make way for a second influx of immigration which requires the same systematic education that their predecessors received. And sooner or later it comes to pass that these new comers are affected with "Wanderlust" and in their place comes a third installment of aliens. And so it goes on. The process of education and of clean up is one unbroken chain.

A glance at Chart I will show that for the past four years (1909-1912) the percentage and number of cases of pediculus capitis among school children have remained substantially the same. In 1909, 1910, and 1911, practically speaking, only the public school children were inspected and, while the number of cases of pediculus capitis as recorded for these years does include a small number that were casually seen at other schools on morning inspection, this number is negligible and for practical purposes would not figure in the percentage. In 1912 the parochial and other schools were inspected.
regularly and systematically, and the proportion of cases of pediculosis in the public and other schools is estimated from the registration, the totals being correct. It will be noted that there has been a gradual decline in the number of cases of pediculosis capitis excluded during 1900, 1910, and 1911, namely, 2,014, 1,497, 1,475. Exclusion takes place only when live pediceli are found, when the case is an aggravated one, or when persistent neglect of treatment is shown. This table shows, therefore, a decline in the severity of the cases if not in numbers. In 1912 the number of exclusions was larger than in any of the previous three years. This is the practical decline from year to year of exclusions from school because of these conditions.

Why is it that trachoma, conjunctivitis, ringworm, scabies, impetigo, etc., have declined so noticeably, while despite all efforts, pediculosis capitis is in so far as numbers and percentage are concerned has remained unchanged? In the first place, the tenement population is aroused only with the greatest difficulty to the realization that pediculosis capitis is of any consequence as far as health is concerned. Many look upon its presence as of minor importance, and tell you that they cannot be “bothered about such a little thing” or that “nits go away without any treatment.” In fact a fairly large number consider it a “good omen,” a sign of health and strength. Often when you suggest that the hair which is matted, twisted, glued together and filled with crusts, nits, pediculi, and pits—the plica polonica—be cut short, or off, you are confronted with the remark that it must not be disturbed, lest the child’s eyesight is weakened, or its strength become lost; or you will be told that the secondary dermatitis is good for the child because the poison is coming to the surface, and that to cure the condition would “drive the poison in.” These people do not fear contagion from this condition. It would seem safer that a goodly number cater to it, were we to judge by the overcrowding and uncleanness at home, the indiscriminate sleeping together, and the common use of toilet articles, such as they are. The contagiousness, the dangers, the unsightliness, and the consequences of the other communicable conditions—trachoma, conjunctivitis, scabies, ringworm, impetigo, favus, etc.—appeal to them more directly and they make greater and more prolonged effort to prevent contact of the one person with the other, to avoid the use of the same toilet articles and to procure treatment. They have a respect for these conditions and an indifference for pediculosis accounted for by the fact that the more aggravated cases were found in schools other than public, schools which had not received the benefit and advantages of regular school and home inspections and instructions for several years past. It will also be noted that on the average five to six instructions and treatments were given to each case. More important and more striking than any figures or charts can show or words describe is this improvement in the type of case, the passing I might say of those cases of pediculosis dermatitis, in which the secondary effects of scratching resulted in pronounced scalp and suboccipital dermatitis, im-

Letters used arbitrarily.

Petiginous crusts, moist exudation, glandular enlargements and suppurition, and scalp abscesses. For this advance, medical inspection of school children is directly responsible.

**chart II** shows that during 1900-1912 the number of cases of pediculosis capitis remained about the same, whereas the actual number and percentage of other communicable diseases of the eyes, skin, and scalp—trachoma, conjunctivitis, ringworm, impetigo, scabies, favus, molluscum contagiosum—declined. **chart III** shows the decline from year to year of the communicable diseases of eye, skin, and scalp, exclusive of pediculosis capitis, and seem rather that a goodly number cater to it, were we to judge by the overcrowding and uncleanness at home, the indiscriminate sleeping together, and the common use of toilet articles, such as they are. The contagiousness, the dangers, the unsightliness, and the consequences of the other communicable conditions—trachoma, conjunctivitis, scabies, ringworm, impetigo, favus, etc.—appeal to them more directly and they make greater and more prolonged effort to prevent contact of the one person with the other, to avoid the use of the same toilet articles and to procure treatment. They have a respect for these conditions and an indifference for pediculosis
capitis which is very striking. Then again the other communicable diseases of the skin and of the eyes are more or less localized; they can be limited by medication given at the hospital or dispensary; they do not spread rapidly as a rule; treatment is more direct; we have parasiticides which can reach them, and, with the exception of trachoma, treatment is given by the nurse at school.

On the other hand, pediculosis capitis is a condition which is not limited and which cannot be treated satisfactorily at the hospital or dispensary or school, as can the other communicable diseases. It requires rather the personal care and attention of the mothers—a care and attention which they are often unable to give, because of poverty, or unwillinging to give, because of ignorance, indifference, carelessness, and neglect.

In pediculosis capitis the mother pediculus leaves trouble in her trail, by the deposit of fifty or sixty ova weekly, which hatch out in three to eight days, and which in turn are capable of reproduction in eighteen to twenty days. It is one continuous performance. Verily, the female of this species is more deadly than the male.

The methods adopted for its control in New York city are as follows: A class routine examination of every child is made by the inspector, in company with the nurse, at the beginning of each school term, and the name of every pupil with nits or pediculi is recorded by code number on the class index card, together with the date of inspection. This initial routine is followed by a monthly routine of the classrooms by the nurse, or more frequently if indications demand it. Each child passes before the inspector or nurse, the girls raising and separating their hair so as to expose the occipital region. Cases which are more suspicious than others with respect to "live stock" are examined separately in the office, outside of the classroom. The children recorded on the class cards are reexamined and instructed at regular intervals, individually and in groups, but always outside of the classroom, and circulars of instruction (English, Yiddish, or Italian) are given and explained in detail. Girls are instructed to keep their hair braided tightly in school, and unbraided and combed daily at home. Consultations with parents at school, or in the homes, are held by the inspector or nurse or both. Exclusion from school takes place only when live pediculi are found, in aggravated cases without live pediculi, and when persistent refusal or neglect of treatment is shown. The word pediculosis is never used; several code numbers, 2, 4, 6, and 8, are adopted to signify this condition, and these numbers are used interchangeably for the different children. Every precaution possible is used to guard the finer sensibilities of the individual pupils, particularly in the case of the girls of the upper classes.

It is true that all this has had a great moral and educational effect upon the parents and pupils so far as the severity of the condition is concerned, but the number and percentage of cases remain almost the same.

Why not better results? Why so many cases? I hesitate to speak of the drug treatment, for so many drugs have been tried by our corps of nurses and inspectors that to enumerate those untried would be the easier task. Crude petroleum, kerosene, carbonate of soda, staphisagria, bichloride of mercury, carbolic acid, spirits of camphor, vinegar, alcohol, ether, benzine, carbine, sulphur, mercurial ointments, borax, potash solutions, essential oils (anise, cinnamon), and proprietary preparations are a few that have been tried for the various stages of this condition with only fair, and often with discouraging results.

DEPARTMENT OF HEALTH
THE CITY OF NEW YORK
DIVISION OF CHILD HYGIENE.

Instructions to Parents on the Care of Children's Hair and Scalp.

Children affected with vermin of the head are excluded from school. The following directions will cure the condition:

Mix one half pint of sweet oil and one half pint of kerosene oil. Shake the mixture well and saturate the hair with the mixture. Then wrap the head in a large bath towel or rubber cap so that the head is entirely covered; the head must remain covered from six to eight hours. (Tincture of larkspur may be used instead of oil mixture. The directions for use are the same.)

After removing the towel, the head should be shampooped as follows:

To two quarts of warm water add one teaspoonful of sodium carbonate. Wet the hair with this solution and then apply castile soap and rub the head thoroughly about ten minutes. Wash the soap out of the hair with repeated washing of clear warm water. Dry the hair thoroughly.

Nits: If the head is shampooped regularly each week as above described, it will cure and prevent the condition of nits.

Issued by Order of the Board of Health.

If pediculosis capitis were only a question of the destruction of the live pediculi, the problem would be comparatively easy, for an application of crude petroleum or kerosene (diluted half with olive oil to prevent dermatitis) usually kills all the live pediculi in twenty-four hours and renders incapable of development those ova which are about to blossom forth as pediculi. It is with the nits that the great obstacle is encountered. The nits are virtually glued to the hair by a material secreted by the pediculus, and for which no one has yet succeeded in finding a good and reliable solvent. But apart from this, the fact remains that no amount, and no kind of treatment at the school will yield results. Pediculosis capitis is a problem of the home, for the home, and by the home; a problem of the child's
brothers and sisters, often of the parents, and grandparents, and frequently of the bedding, the clothing, the towels, the combs, the brush, and other household utensils. It is a common experience to have a child "cleaned up" at the school by the nurse, only to return home, and become re-infected by other members of the family.

In an investigation of the home conditions of 161 families in which the school child had pediculosis capitis I found (Chart X) that the general condition of the home, of the bedding and of the clothing was filthy in eighty-seven cases, dirty in twenty-nine cases, fair in twenty-three cases and clean in twenty-two cases. In about one third of the cases (56 out of 161) which could be examined satisfactorily at home, the mother, the grandmother, or other children, had pediculosis of the scalp. In several instances the conditions were described as "horrible," "alive with lice." In a fair proportion of cases—from thirty to forty per cent.—pedi-

culi were found on the bedding; while overcrowding during sleep, that is, one or two beds, or one bed and a couch, or an improvised bed made out of two chairs, often in one or two rooms, for the use of four to six or seven members of the family, was very common—from sixty to seventy per cent. Oftimes it was found that the mother was working, because the father was dead or had deserted the family, and the children were thus thrown upon their own resources for head cleanliness.

The use of the common family comb, brush, towel, and wash cloth, as channels of conveyance, could easily be ascertained. Even that mighty weapon for removing nits—the fine toothed comb—was frequently old, broken, filthy, "just lost," or they "couldn't find it." Many times it seemed as if the mother did not want to learn, for it was a common observation that many mothers used a dash of kerosene in some cold water as a head wash, feeling that this was the proper and only necessary procedure. Many mothers were too lazy or too indifferent to look after the heads of the children. This was especially noticeable with the older girls, whom the mothers frequently told to look after themselves; the result was that the younger children, who were taken care of by the mothers, were found to be cleaner than the older girls, who often neglected to attend to their own scalp properly.

What therefore can one hope to accomplish with the school child per se, when it is exposed day in and day out to home reinfection. We have had many mothers' meetings to emphasize this question, but I am convinced, more than ever, that group teaching in this matter is not and never will be a success, and that what is required is individual personal instruction in the home by the nurse, and a practical demonstration by her of the ways in which the disease spreads, and the manner in which it can be prevented and cured. The parents must be shown that for mutual protection it is necessary to look after not only the school child, but after all members of the family, all the bedding, articles of clothing, furniture, and toilet articles. In truth, unless we can reach and destroy the pediculus soon after it alights on the head of the child the task is almost a hopeless one. The pediculus capitis recognizes no social distinction. Rank offers no protection. Therefore every parent should examine and comb carefully and thoroughly the heads of all the school children, before they retire at night, and try to discover, remove, and destroy the pediculus before the ova are deposited.

In an investigation of the home conditions of sixty families in which the school child was free from pediculosis capitis (Chart X) the following facts were ascertainable: Dirty in six cases, fair in twelve, clean in thirty-four and very clean in eight. It has seemed to me that, with the large number of cases on hand, we have unwittingly and unconsciously spent too much time and energy in an effort at eradication in the school. We have "swatted" or tried to "swat" the pediculus and nit in the school, instead of beginning at the other and proper end, by "swatting" and treating the breeding place—the home. I do not know but what a more fitting title for my paper would have been "Pediculosis Capitis in the Homes of School Children."

The treatment of any individual school child, or any number of school children, is insignificant when compared with the treatment of the home—infected parents, infected brothers and sisters, infected bedding, clothing, toilet articles, et al. To accomplish results we must show the parents the way. We must show them that local medication of all kinds is far more difficult, and far more thankless, than they are led to believe; that the greatest hope lies in prevention, and that the entire
family and the home must be looked upon as a unit, in so far as cleanliness is concerned.

In New York City one of the most interesting observations has been the relative freedom of the colored school children from pediculosis capitis. In some schools where the majority, or a large proportion of the pupils is colored, the number of cases of pediculosis capitis among them can often be counted easily on one or both hands. Chart IX shows that of 28,791 children in sixteen public schools, 2,579 were colored and 26,212 were white, and that of this number thirteen cases of pediculosis capitis were found in the colored children and 4,340 cases in the white, a percentage of 0.5 in the colored as against 16.5 in the white. I will not say that this is due entirely to better home conditions, although, in my experience, the homes of the colored population as a class are more cleanly than those of the majority of our alien population.

In the homes of twenty-seven colored school children in whom no pediculosis capitis was present, the conditions (Chart X) as follows: Dirty, one; fair, two; clean, twenty-two; very clean, two.

Of these twenty-seven children, all except three had kinky hair. In the homes of thirteen colored children in whom pediculosis capitis was present, the conditions were as follows: Dirty, seven; fair, two; clean, four. In three cases it was noted that “the mother is almost white and has straight brown hair” and “the children have long, curly hair, not kinky.”

I have been forced to look for other reasons for this infrequency. It has seemed to me that many colored mothers realize that the color of their children is itself a handicap to their school progress, because of aversion in some quarters to their race, and that under the best circumstances their children are apt to be laughed at and teased. It is more than likely, therefore, that they exert an unusual effort to prevent the occurrence of pediculosis by examining and combing the hair of the children daily, and thus spare them the burden of further annoyance. On the other hand, it may be that the color of the scalp or the odor of the skin, that is, the sebaceous glands, is disagreeable to, or as Fox puts it, “has a discouraging effect upon” the fastidious pediculus, or that the crispiness of the hair does not permit the glutinous material of the ova to cling fast to it. Or it may be that the custom of the girls to keep the hair tightly braided and frequently combed, in order to straighten it, prevents the pediculi from finding a suitable lodging place.

Dr. W. L. Funkhouser, of Rome, Georgia, wrote to me: “In reply to your letter of recent date will say, that I too have been interested to know why I found so little pediculosis among the colored children. I have about 800 colored and 1,800 white: during the past month I included thirty-three white, and not a single colored child. The colored principals and teachers tell me that they very rarely have seen any in the colored children. I have talked to some of the old slaves. They say that long ago it looked like the ‘niggers heads breded ‘em,’ and gave as their reason the effort to-day to straighten the hair. I found on query that fully one half used some preparation of some kind on their hair, and spent much time combing. They will neglect their bodies for their hair.”

Dr. Howard Fox, in his Study of Skin Diseases in the Negro, says: “Doctor Carmichael informs me that the negro women in Virginia take a special pride in keeping their heads and those of their children free from lice. Doctor Pendergast, of Mem-

who should give individual instruction to the parents. Their hands should be upheld by the principals and teachers. This may take up a little time, but it will prove well worth while, for it is surprising to see what regard many parents have for the advice and authority of the principal. That the influence of the immediate school authorities has a pronounced and direct influence upon this condition may be seen from Chart IV, in which are listed various schools harboring the same type of children in practically the same section of the city, with

*Fifty-four had kinky hair; six straight hair.

Thus the idea—the thought of cleanliness—is kept constantly before the pupils, and where cleanliness reigned, pediculosis will eventually cease to exist.

These charts also serve to show what systematization means in any school and how despite the talk in some quarters that medical inspection of school children interferes with the regular routine of school work, a great deal can be done by the interested cooperation of the principal. I venture to suggest and advocate that we have charts in each classroom to tally the number of cases of pediculosis capitis, under the caption "Clean Scalp" (Chart VIII). As each routine inspection of the

COLORED CHILDREN: Children with pediculosis capitis. 13 Homes. | Children free from pediculosis capitis. 27 Homes.

Girls. I have frequently used this as an argument to awaken an increased pride in the girls of the school, by asking them if they were going to have the boys outdo them in cleanliness.

At some of our schools, in addition to the instruction and advice of the inspector and nurse, personal hygiene of the mouth, eyes, scalp, body, shoes, and clothing is taught and controlled systematically by means of daily classroom inspection and daily drills conducted by the teacher, and supplemented by a monitor or captain for each class. In addition to this the principals interview not only the pupils, but the parents as well, and impress upon them the need and importance of cleanliness. These exercises or drills stimulate in pupils lessons of personal and household cleanliness, lessons which they bring into their homes and help to have carried out. These exercises are furthermore controlled by the use of separate charts (Chart VII) for cleanliness of the various parts of the body (face, arms, neck, hands, nails), and for the various articles of clothing (shoes, jackets, waistcoat, etc.). This method, this stimulus to keep clean, has reduced in several of the schools not only the number of cases of pediculosis capitis, but also the number of other communicable diseases of the skin, scalp and eyes.

similar home surroundings, and in which the cooperation of the principal is good, or poor.

In the schools noted the nurses and inspectors are practically of equal calibre, and the methods of examination and interpretation of the findings are substantially the same.

I do not want to convey the impression that exceptions to this do not occur, and that many other factors must not be taken into consideration. But the relation between school cooperation and the percentage of pediculosis capitis is striking enough to warrant attention. Chart VI shows the well known fact that pediculosis capitis is more common among girls. It has frequently used this as an argument to awaken an increased pride in the girls of the school, by asking them if they were going to have the boys outdo them in cleanliness.

At some of our schools, in addition to the instruction and advice of the inspector and nurse, personal hygiene of the mouth, eyes, scalp, body, shoes, and clothing is taught and controlled systematically by means of daily classroom inspection and daily drills conducted by the teacher, and supplemented by a monitor or captain for each class. In addition to this the principals interview not only the pupils, but the parents as well, and impress upon them the need and importance of cleanliness. These exercises or drills stimulate in pupils lessons of personal and household cleanliness, lessons which they bring into their homes and help to have carried out. These exercises are furthermore controlled by the use of separate charts (Chart VII) for cleanliness of the various parts of the body (face, arms, neck, hands, nails), and for the various articles of clothing (shoes, jackets, waistcoat, etc.). This method, this stimulus to keep clean, has reduced in several of the schools not only the number of cases of pediculosis capitis, but also the number of other communicable diseases of the skin, scalp and eyes.
Sobel: Pediculosis Among School Children.

if for the sake of an argument we concede that these charts would make the child "feel ashamed," or "afraid of being picked out," if they would be the means of making him "clean up," then surely these are the best arguments for their adoption. The common sense view of the matter is that pediculosis capit is a public danger and as such needs a public warning, "and the more public the place the more effective the warning."

Cases of direct school infection are relatively uncommon. Where pupils come in close contact during play, or where head to head contact takes place, the migration of the live pediculus does occur. Infection via the clothing, especially head gear, is more common and occurs more frequently with girls than with boys. The last keep their hats or caps either in their coat pockets or in their desks, while the hats, capes, and cloaks of the girls are kept closely together in one closet, usually dark and poorly ventilated. Much could be done in a preventive way at school by providing separate lockers, or by having separate hooks, bags, or other compartments, for the hats and cloaks of the girls. If separate bags for all girl pupils are considered too radical or too expensive, let us have them at least for those pupils known to be infected. In schools where girls are adept at sewing these could be easily provided.

One word as to actual treatment. The destruction of the pediculus is relatively simple. When nits are numerous local medication is a thankless task. With boys the problem offers few difficulties, for clipping off the hair gives the easiest, most rapid and most satisfactory results and no opposition, as a rule will be offered. With girls, however, clipping off the hair should be the last resort. They resist any such interference. All girls should have their hair braided tightly in the classroom, and unbraided and combed at home every night, for inspection, for care, and for treatment.

After many years of experimentation with any number of drugs, I am of the opinion, that there is but one successful way of removing the nits—other than cutting the hair—and that is by mechanical means. Patient, persistent, painstaking removal of the nits strand by strand, with the hand, sand paper or a fine toothed comb is the only successful plan for pronounced cases. The various drugs may loosen a few nits, but the majority will succumb only to forcible eviction. This is something that must be taught, explained, and shown to the parent.

Conclusions.

The conclusions which have been forced upon me, as a result of some eleven years of personal observation and experience with pediculosis capit is among school children, are as follows:

1. The severity of the cases and the number of children excluded from school have been materially influenced for the better, by the methods used—morning inspection, periodic classroom examination, individual and group instructions of pupils at school, braiding of hair at school and unbraiding at home, consultation with parents at school and at home, practical demonstrations in the house, exclusion of children with live pediculi, aggravated cases, and those who persistently refuse treatment, co-

operation of principals and teachers, mothers’ meetings, distribution and explanation of circulars of information, and instruction in personal and home hygiene and in cleanliness.

2. Pediculosis capit is of importance from the standpoint of general cleanliness, disturbance of the general health, transmissibility of disease, interference with school attendance, production of secondary infections, and lowering of the child’s mental equilibrium.

3. The more stationary and the more homogeneous the population and the less the influx of immigration, the easier and more successful the control of this condition.

4. While the number of other communicable diseases of the scalp, skin, and eyes has gradually diminished from year to year, the number and percentage of cases of pediculosis have practically remained stationary. This is accounted for by the fact, that the tenement population consider pediculosis of little import, not dangerous, and frequently a sign of good health, while they fear the other forms of contagion, and take all precautions to prevent their spread and to effect their prompt cure. The other communicable scalp, skin, and eye diseases are frequently treated and controlled at the school, and are more localized, and more readily accessible, and responsive to treatment.

5. Treatment of the school child alone is of little value in the control of pediculosis capit. Other members of the family, the clothing, bedding, combs, brushes, towels, washcloths, etc., must be kept clean. The solution of the problem is the home. The school is but a means to an end.

6. Unfavorable home conditions are often the result of poverty per se; quite as frequently they are due to carelessness, indifference, ignorance, irresponsibility, and neglect.

7. The destruction of the pediculus is relatively easy. The eradication of the nits by local medication is unsuccessful. Removal of nits is accomplished best by mechanical means.

8. Personal individual instruction of the mother in the home by the nurse, and practical demonstrations by her as to prevention and treatment, are the means which assure success. Mothers must be taught to look after the older school girls, as well as the younger members of the family. The common family brush and comb must be discontinued and the nurse must show the dangers of their use and the method of transmissibility by this and other channels.

9. Instructions per se even if printed in the mother tongue of the people are useless. These must be supplemented by personal instruction. Circulars printed in English are of greater value, because they are read and explained by the school child—the messenger of education for most of the households.

10. The cooperation of the principals, teachers, and of the pupils is essential to success. Individual advice to pupils and mothers, practical lessons, and drills in personal hygiene, the use of charts in order to ascertain the status of, and to inspire the thought of cleanliness in the pupils of the class, have an effect which is difficult to overestimate.

11. In schools situated in the poorer sections of
the city, where home conditions of the pupils are the same, and where both boys and girls attend, the percentage of pediculosis capitis in those schools wherein the cooperation is good, is less than in those wherein the cooperation is poor.

12. In the schools of the better sections of the city where boys and girls attend, the percentage of pediculosis capitis is far less than in the poorer sections, irrespective of the cooperation of the school authorities, because of improved home surroundings and better financial circumstances. School cooperation here is almost an inconsequential factor.

13. The percentage of pediculosis capitis in schools harboring boys only is less than in those harboring girls only.

14. Better facilities should be provided at the schools for a separation of the clothing and head gear of the pupils, especially that of the girls. Separate lockers, hooks, bags or other containers should be installed, at least for children known to be infected.

15. Prevention of the condition is easier than its cure. Education will accomplish what drugs have failed to do.

16. The prejudices and superstitions surrounding this condition must not be laughed and scoffed at by school inspectors or nurses. This method will never win over the mother.

17. The dangers of general infection, of loss of hair, of disease of the scalp, of infected glands with resulting scars and deformity, of predisposition to tuberculous glands—in a word, all the dangers of the condition must be brought home to the parents in a quiet, and confiding, yet impressive, and firm way. Give them something to think about, and show them that the condition is not one to make light of at any time.

18. Pediculosis capitis is very infrequent among the colored school children of New York city. It occurs with greater frequency among those with soft straight hair than in those with the kinky variety and among those children born of white mothers or light colored negroes. This infrequency in my opinion is due in large measure to the constant combing to which this race subjects the hair in order to straighten the kinks.

19. And finally, with apologies to Owen Meredith:

You may talk about poetry, music, and art.
You may talk about conscience and talk about heart.
You may talk about knowledge and talk about wit.
The bane of inspection is the ubiquitous XIT.

Kansas City, Mo.

Instructor of Internal Medicine, University of Kansas.

The limitations of this contribution I have tried to indicate in the title. The writer is not a radiologist. He approaches the subject from the clinical viewpoint and attempts to inquire in a critical spirit just the place to which the x ray is entitled in the armamentarium of the diagnostician. No consideration is, of course, given to such diseases of the bones and joints as might come within the province of the general internist. Furthermore, we attempt here no formal review of the literature; the basis of our remarks and our conclusions is our personal experience. We have been fortunate in this work in having had the help and guidance of an experienced radiologist, Dr. E. H. Skinner, and of his constant helpfulness, enthusiasm, and courtesy we wish to make here grateful acknowledgment.

Three conditions we will not consider at all: Aneurysm of the thoracic aorta; stricture, dilatation, or diverticulum of the esophagus, including cardiospasm; stone in the kidney. In all of these the prominence of the x ray is so generally acknowledged as to need no comment.

The technic of these examinations we will only indicate in brief. Plates were used very little. The fluoroscope was used exclusively, and plates only for recording some condition permanently for reference. In the fluoroscopic method it is of the utmost importance for the operator and clinician to stay in the dark room for some time, in order to allow the eyes to accommodate and the retina to become sensitive to somewhat darkened images. The patient is stood up between a Mueller water cooled tube and the fluoroscopic screen, which is movable and provided with a shutter diaphragm, so that a small field can be studied to the exclusion of other parts, if desired. This gives the effect of a higher power of the microscope upon a slide. (Fig. 1.)

Every clinician should, of course, become familiar with the normal appearance of the chest in the fluoroscopic picture. The advantages of the fluoroscopic method are, first, that the patient can be turned around, and the chest examined from several elevations, in a short time; second, that a portion of the field can be minutely examined with the closed shutter; third, that the movements of the diaphragm can be observed; fourth, that the spicules can be observed in inspiration and expiration, a very important consideration in early pulmonary tuberculosis; fifth, that the movements of the heart and aorta may likewise be observed. All these things are of course lost upon plates. The same general advantages hold good in the examination of the abdomen as in plates it is impossible to see the movements of the stomach and small intestine, and certain special relations are lost.

Doctor Skinner has designed an ingenious arrangement for giving the patient three bismuth meals which will serve for one examination. The patient eats a bismuth meal (two ounces of bismuth oxychloride in twelve ounces of buttermilk, malted milk, or cream of wheat porridge) at 10 a. m. of the previous day and 4 a. m. of the day of examination, and presents himself for examination at 10 a. m., when another meal is given. Thus we are able to see a meal in the stomach and observe its contour and movements, we are able to observe where the six hour meal, which should all be in the cecum and ileum, is, and are able to see the shape and position of the large intestine from the twenty-four hour meal.

Before beginning a formal discussion of some conditions of the chest and abdomen, certain general considerations should be touched upon which would
be out of place in that review. For in what follows the point of view to be insisted upon is that we wish to inquire what things the x ray can tell us which we can find out by no other method—in what conditions it plays the rôle that the Widal reaction or blood culture plays in typhoid fever. But aside from actual diagnosis, the x ray can teach the clinician certain phases of physiological pathology, can act as an autopsy, can show him fascinating things which he can see nowhere else so graphically. The economic problem enters here. We are not justified in submitting many of our patients to the time and expense of an x ray examination just to show us living pathological anatomy; but under conditions when this consideration does not enter—as for instance in the service of a general hospital provided with adequate fluoroscopic facilities—we can recommend it to every clinician in the certainty that he will be abundantly rewarded. Merely to catalogue a list of things with which he may be perfectly familiar at the autopsy table, in the physiological laboratory, or from the literature, let us name the wave of the heart beat, the action of the auricles, the pulse of the aorta, the movements of the diaphragm, the position of the fluid in pleural effusion, the action of the remains of the contracted lung in pneumocephalus, the emptying of a bronchiectatic cavity on coughing, the act of swallowing, the peristalsis of the stomach, and the method the stomach employs of emptying its contents into the duodenum, the physiology of vomiting, which we have once or twice seen, the normal anatomy of the large intestine, and the action of enemas.

In this connection it is worth recommending that plates of cases which are being examined be used in teaching physical diagnosis. The student goes over a chest and reports his findings, say in a case of pulmonary tuberculosis; he is then shown the plate of that case and allowed to draw his own conclusions. It is a vast improvement over the mere statement of the instructor that such and such conditions are present which he did not find.

**DISEASES OF THE CHEST.**

The orthodiagram is an instrument for accurately measuring the size of the heart. In order to do this a parallel ray must be thrown, by means of a small opening from the x ray tube, through the chest, and be received by the operator, so that the shadow of the heart can be outlined. The ingenious instrument of Groedel is satisfactory for this purpose. Comparisons of orthodiagrams with the percussion boundaries of the heart, made by careful and competent percussors, have demonstrated that in normal hearts the percussion outline is surprisingly exact. In hypertrophied hearts, however, the percussion is in most cases very far wrong, especially on the right side. These things, though, are of somewhat academic value. By the ordinary methods of heart examination we can learn very well what is essential to learn about the case. To our physical examination of the heart, at any rate, the x ray can add little of real value in any given case. (Fig. 2.)

It is true that when one sees a few cases of enormous dilatation or hypertrophy on the fluoroscope screen, when one sees, let us say, mitral insufficiency and then a mitral stenosis, he obtains an idea of their anatomy and physiology more graphically than in any other way. But this belongs more to the study of pathological physiology with the x ray referred to above than to real help in a diagnostic problem.

![Fig. 1.—Becleré fluoroscopic apparatus.](image1)

![Fig. 2.—Normal chest.](image2)
To this category, too, we believe, belong the studies on mitral stenosis of Vasquez and Bordet (5) in which they describe the small left ventricle and large left auricle. Here also belongs Beck's (6) interesting study of the small heart of pulmonary tuberculosis. It has been suggested that the orthodiagram may give us the earliest indication of beginning loss of compensation. Some radiologists once believed that it might be used to determine auricular fibrillation and heart block. We have no experience here, and have no inclination to gain any. We have a far more likely method of determining the condition of the myocardium (bundle of His, etc.) by the use of the polygraph, and this, combined with our methods of physical diagnosis, gives us so much information that the use of the orthodiagraph is not essential. In pericarditis, however, and especially pericarditis with effusion, it may be absolutely diagnostic. All know the doubtful value of percussion in these cases. Here the orthodiagraph can give us positive information which we can obtain in no other way.

PULMONARY TUBERCULOSIS.

No idea of the use of the x ray in pulmonary tuberculosis is of any value unless we are careful to distinguish between early, middle, and late cases. For present purposes, we mean, by early cases, a "slight initial lesion, in the form of infiltration, limited to the apex or a small part of one lobe," a pure infection with tubercle bacilli, without mixed infection and little constitutional disturbances. (Fig. 3.) By middle cases we mean a definite, though localized, consolidation, usually confined to one or two apices, and with moderate constitutional disturbance. By late cases we mean the familiar picture of diffuse chronic caseous bronchopneumonia, with cavity formation and widespread tissue involvement.

Taking the last of these first, it has, of course, been thoroughly established that the x ray is capable of revealing all the tissue changes present in these advanced cases. It throws a shadow of the caseous and the consolidated areas on the plate, and it reveals the presence, location, and size of cavities, often when they do not reveal their presence by the methods of physical diagnosis. In the moderately advanced cases, too, it usually shows the shadow of the consolidation in the apices. Sometimes the shadow is faint, but here we have the additional evidence of the enlargement of the glands at the hilus of the lung and their extension directly from the hilus to the affected apex. I think I have never failed to see a definite shadow cast by the x ray in any case where there were definite and unmistakable evidences of involvement, in this general type of case, and often, I may say, the x ray has revealed a greater extent of disease that the physical signs justified me in believing was present. (Fig. 4.)
